Fourier transform methods changed all that. Versatile pulse methods could now be used to study complex molecules. Spectra could be obtained rapidly in order to follow fast reactions or to use time-averaging techniques effectively to improve signal-to-noise ratio (S/N). Developments of NMR in chemistry and physics had proceeded along quite separate paths, but the advent of FT methods brought these two approaches to NMR together.

The name of Richard Ernst, above all others, is associated with FT NMR. Indeed, in 1991 he received the Nobel Prize in Chemistry for his work in developing FT methods, from the first seminal paper with Wes Anderson to his drive to make two-dimensional NMR a reality (as described in a later section). Ernst was not alone, however, in developing FT NMR. In Section 4 we saw that physicists, such as Herman Carr, had done 'mental' Fourier transforms to interpret the results of simple pulse experiments and that Lowe and Norberg had formulated the FT relationship between the FID and the slow passage spectrum in a solid.¹³⁶

Table 1 High-Resolution NMR Spectrometers^a

<i>Varian Associates, NMR Division (Palo Alto, CA)</i>	
1949	First commercially available NMR instrumentation
1952	First high-resolution NMR spectrometer (30 MHz)
1956	40 MHz spectrometer
1958	HR-60 NMR spectrometer
1961	A-60. Easy to operate, 60 MHz proton only
1964	HR-220. First commercial superconducting NMR spectrometer. Proton NMR only
1965	HA-100. Internal homonuclear field-frequency lock
1966	T-60. First permanent magnet NMR spectrometer for proton observation at 60 MHz
1969	XL-100. Initially CW, later modified for FT. Initially $^1\text{H}/^{13}\text{C}$ observation, later multinuclear capability (Gyrocode observe accessory)
1972	CFT-20. First routine ^{13}C FT NMR (20 MHz) spectrometer for organic chemists
1975	FT-80. Evolved from CFT-20 to provide multinuclear capability. 80 MHz ^1H
1975	EM-390. Permanent magnet CW NMR spectrometer for proton observation at 90 MHz; later options for ^{19}F and ^{31}P
1978	XL-200. Superconducting, multinuclear
1982	XL-300. Multinuclear and solids capability
1983	XL-400. Multinuclear and solids capability
1985	VXR series (200/300/400/500). Replacement for XL series with design improvements
1986	Wideline solids accessory for VXR series spectrometers
1986	Gemini-200. Easy-to-use, low-cost superconducting $^1\text{H}/^{13}\text{C}$ spectrometer
1987	VXR series S. Enhanced version of VXR series with UNIX-based SUN workstations
1987	Gemini-300
1988	VXR-600S.
1989	Unity series (200/300/400/500/600). Sun workstations; multinuclear; solids and micro-imaging capability
1989	Broadband Gemini series (200/300).
1989	Ultrashims. Introduction of RRI matrix shim system for improved magnet homogeneity
1991	Gemini-400. Equipped for indirect detection and multinuclear operation.
1992	Unity-plus series (200/300/400/500/600/750). Multiple rf channels; pulsed field gradient accessory; nano-probe
1993	Unity-plus 750. First commercial 750 MHz spectrometer installed
<i>Perkin-Elmer (Beaconsfield, UK)</i>	
1961	R-10. First commercial NMR spectrometer (40 MHz, later 60 MHz) with permanent magnet. Precalibrated strip-chart recorder.
	First homonuclear spin-decoupling accessory. High-performance variable-temperature probe
1967	R-12. Permanent magnet. First NMR spectrometer (60 MHz) with solid-state electronics. Spin-decoupling or field-locking. (Over 350 R-12s sold worldwide)
1972	R-32. 90 MHz proton only. CW, later FT. First 90 MHz permanent magnet instrument. (Over 150 R-32s sold worldwide)
1976	R-34. 220 MHz superconducting spectrometer. Sold for under \$100k. Only seven units sold in the United Kingdom
1979	Perkin-Elmer withdraws from the NMR business having sold over 600 spectrometers worldwide.
<i>Japan Electron Optics Limited (JEOL) (Tokyo, Japan)</i>	
1962	C-60. 60 MHz, electromagnet, high-resolution proton only
1965	C-60H. 60 MHz, high-impedance electromagnet. Variable temperature
1966	C-60HL. Used low-impedance magnet. Other frequency probes available as options
1968	PS-100. Research high-resolution NMR spectrometer for proton observation (CW)
1970	MH-100. Tabletop routine high-resolution spectrometer, proton only. CW
1973	PFT-100. PS-100 with pulsed-FT accessory added
1973	FX-60. Proton (60 MHz)/ ^{13}C pulse FT. Complete computer control. $^1\text{H}/^{13}\text{C}$ dual switchable probe, noise-decoupling, variable temperature. Light-pen operator interface
1975	FX-100. 100 MHz. Similar to FX-60. Quadrature detection
1976	FX-60Q. Same as FX-60 but with digital phase shifter for quadrature detection
1978	FX-90Q. Proton (90 MHz)/ ^{13}C , later upgraded to multinuclear operation. Frequency synthesizer-based
1980	FX-200. Broadband, multinuclear. Oxford 4.6 T superconducting magnet
1981	GX series (200/270/400/500). Improved data system and modular design. Broadband
1986	GSX series (200/270/400/500/600). Improvement on GX Series. Addition of GSX-600
1990	CPF series (270/400). Lower cost, automated version of GSX series for routine use
1991	ALPHA series (400/500/600). Pulse-shaping capability, three channels, gradient drivers. VMS data system
1992	CPF/EX series (270/400). Upgraded CPF, with inverse detection and 3D capabilities
1993	Eclipse series (270/400). Improved CPF/EX series. UNIX-based Silicon Graphics workstation.
1994	Flexible, complete computer-tunable broadband probe, ranging from ^{31}P to ^{15}N
<i>Hitachi Instruments (Tokyo, Japan)</i>	
1963	H-60. High-resolution, permanent magnet
1966	R-20. 60 MHz. First permanent-magnet system with proton external lock
1968	R-20A. Same as R-20, expanded to observation of ^{19}F , ^{13}C , ^{31}P , ^{11}B . CAT optional
1969	R-22. First permanent-magnet instrument at 90 MHz
1971	R-24. 60 MHz, proton only. Permanent magnet. Using 4-mm sample tubes

Table 1 *Continued*

1972	R-24A. Same as R-24, but using 5-mm sample tubes and flatbed X-Y recorder
1972	R-22FT. R-22, with FT capability added. First permanent-magnet FT system
1972	R-40. First routine 90 MHz small permanent-magnet system. CW
1975	R-42FT. Replaced R-22FT
1975	R-24B. Replaced R-24A, with improved sensitivity
1978	R-600. First small permanent magnet 60 MHz FT-only spectrometer equipped with ^2H internal lock
1978	R-900. First permanent-magnet system for proton (90 MHz)/ ^{13}C FT-only. $^1\text{H}/^{13}\text{C}$ switchable probe
1980	R-90H. Proton (90 MHz)/carbon pulsed-FT. Computer-controlled multinuclear accessory
1981	R-250H. Pulsed-FT multinuclear superconducting NMR system
1987	R-1500. Replaced R-600. Proton only, 60 MHz, pulsed-FT
1988	R-1100. First 60 MHz computer-controlled multiple scan (CW) spectrometer
1988	R-1200. First commercial spectrometer with rapid scan-correlation method. 60 MHz, proton only. Permanent magnet
1989	R-1900. Replacement for R-90H. $^1\text{H}/^{13}\text{C}$ observation
1989	R-3000. Replacement for R-250H. Proton (300 MHz)/ ^{13}C . One-year liquid helium hold time. Optional solid state CP MAS

Bruker Instruments (Billerica, MA), Bruker (Karlsruhe, Germany), Spectrospin (Zurich, Switzerland)

1963	First commercial pulsed NMR spectrometer
1967	First multinuclear NMR spectrometer (HX and HFX series)
1968	HFX and HX series, 60 and 90 MHz spectrometers (CW) introduced in the US
1969	FT accessory for HFX and HX systems
1971	HFX and HX series (180/270/360). Superconducting NMR systems
1972	WH Series (60/90/180/270/360/400). First fully high-resolution FT-only spectrometer using the BNC-12/BNC-28/Aspect 2000 data systems
1972	SXP series. High-power pulse system
1973	WP series (60/80/100/200). High-resolution research and routine NMR spectrometers
1977	WM series (100/200/250/270/300/360/400). High-resolution research spectrometers
1978	CXP series (100/180/200/270/300). For state-of-the-art solids experiments
1979	WM-500. First commercial 500 MHz spectrometer
1981	Automatic sample changer. Allowed truly unattended system operation
1982	AM series (200/250/300/360/400/500). High resolution, broadband
1984	MSL series (90/100/200/300/400). Solids analysis: wideline, CP MAS, CRAMPS
1984	AC series (80/100/200/300/400). Economical routine automated spectrometer
1985	Microimaging. AM and MSL series
1987	AM-600. First commercial 600 MHz spectrometer
1988	MSL-500. First commercial 500 MHz wide-bore spectrometer delivered
1988	AMX series (200/300/360/400/500/600). Liquids, solids, and microimaging experiments. Aspect X-32 data system (UNIX-based)
1991	Gradient spectroscopy. Available for the AMX, MSL, and AC series.
1991	Solids automation. Complete computer control of sample insertion-ejection and spinning
1992	ARX series (200/300/400/500). High-performance, high-resolution spectrometers
1992	ASX series (200/300/400/500). High-power solids spectrometers. CP MAS, CRAMPS, DOR (double-oriented rotation), wideline. High-temperature probes ($>1800^\circ\text{C}$)
1992	Digital lock in AMX series. Improved field/frequency stability
1992	First NMR spectra at 750 MHz acquired on an AMX-750
1992	Bruker acquires NMR and chemical shift imaging businesses from General Electric Co.
1993	DMX, DRX, DSX series (300–750 MHz). New generation of digital spectrometers with extensive use of distributed processing with fast signal processors
1994	DPX series (200–400 MHz). Two-channel digital spectrometer for routine studies
1994	QXI inverse probe. Faster spin-transfer experiments with four nuclei (^{31}P , ^{15}N , ^{13}C , ^1H)
1995	First 800 MHz spectra, DRX-800

GE NMR Instruments (Fremont, CA)

1972	TT-100 FT accessory. Marketed by Transform Technology Inc. (TTI) for Varian XL-100 and HR-220 spectrometers
1973	TT-7 FT accessory. Introduced by Nicolet Technology Corporation (NTC, formerly TTI) for use on Varian T-60 and Perkin-Elmer Permanent-magnet spectrometers
1973	TT-14 FT console. For use with 1.4 T electromagnet systems
1975	NT-150. $^1\text{H}/^{13}\text{C}$ NMR spectrometer using Nalorac superconducting magnet introduced by Nicolet Magnetism Corporation (NMC, formerly NTC)
1976	NT series (200/300/360/500). Narrow- and wide-bore Oxford magnets
1983	QE (quick and easy)-300. Easy-to-use $^1\text{H}/^{13}\text{C}$ NMR spectrometer
1983	Magnetism Division of Nicolet (NMC) purchased by General Electric Co.
1984	GN series (300/360/500). Replacement for NT series. Multinuclear, multidimensional NMR with solids capability.
1988	OMEGA series (300/360/400/500/600). Design improvement for GN series. UNIX-based SUN 3/160
1992	GE exits the NMR business in August, selling its technology to Bruker.

Chemagnetics (Ft. Collins, CO)

1978	Company incorporated
1979	CP MAS probes. Double air-bearing design

Table 1 Continued

1980	CP MAS accessory. Sold by JEOL with FX-60QS, FX-100, and FX-90Q
1981	High-resolution Nb/Ti superconducting magnets
1983	A-200. First easy-to-operate, 200 MHz FT spectrometer priced under \$100k
1984	M-100/M-200. First routine, low-cost (\$125k) ^{13}C only, 'solids' spectrometer
1986	CMC-200/-300. Versatile analytical 'solids' spectrometer with broadband 'X' rf channel
1987	CMX Series. Flexible research-grade 'solids' spectrometer
1989	CMX-500. First instrument shipped
1989	Majority holding in Chemagnetics purchased by Otsuka
1990	First overseas CMX shipment made to Japan and Europe.
1991	CMX series (phase II). Major system enhancements. Liquids microimaging, DOR, large volume, high-temperature performance. Choice of computer workstations

IBM Instruments, Inc. (Danbury, CT, and San Jose, CA)

1980	IBM Instruments, Inc., a wholly owned unit of IBM, organized and purchased non-controlling interest in Bruker. Instruments to be manufactured by Bruker to IBM specifications.
1980	NR-80. Electromagnet-based, multinuclear, later fitted with CP MAS capability
1981	SY series (100/270). Superconducting multinuclear liquids NMR spectrometers
1981	Solids accessory for variable-temperature CP MAS capability
1985	AF series (80/100/200/250/300). Multinuclear, single-synthesizer design. Highly automated operation. This was IBM's most successful line of NMR spectrometers.
1985	PCNMR. PC-based off-line processing program for handling routine 1D NMR data sets
1987	The company announced that it would exit the instrumentation business.

The development of FT NMR as a practical method owes much to the availability of on-line computers in the 1970s, however primitive they may seem by current standards. In this section we summarize the unfolding of FT methods (and other related techniques) in the context of the knowledge and technology available at the time.

Ernst and Anderson's Famous Paper

When Richard Ernst joined Varian Associates in 1963 to work with Wes Anderson, the problem of low sensitivity remained central to the further development of NMR methods. As we saw in Section 5, special purpose time-averaging computers had just become available and offered the possibility of a significant improvement in S/N if enough repetitive spectral scans could be co-added. A typical 500–1000 Hz wide ^1H NMR spectrum, however, required about 1 second per Hz to scan without spectral distortion. Even if some broadening and distortion could be tolerated at least 100 s would be required for each scan, so a practical limit of about 500 scans could be accommodated in an overnight experiment resulting in an improvement of S/N of only about a factor of 20. For ^{13}C NMR, which was beginning to be of great interest in organic chemistry, the problem was exacerbated: the frequency range was greater (about 3000–5000 Hz), the inherent sensitivity of the nucleus is lower than that of ^1H by a factor of 64, and the natural abundance is only 1.1%. Ernst examined the factors important in optimizing scan rates, but any potential improvements seemed marginal. (Only several years later would Dadok and Sprecher show how very rapid scans could be treated mathematically to generate undistorted spectra, as we discuss later.)

What was needed was a method for *simultaneously* exciting nuclei over a range of resonance frequencies and somehow disentangling their nuclear induction signals, rather than *sequentially* bringing them into resonance by a slow field or frequency sweep. Years earlier, Russell Varian had suggested the idea of exciting the nuclei with a wide band of frequencies

from a noise generator, recording the signals (heterodyned down to audiofrequencies) on magnetic tape, and playing back the tape at different speeds to extract the individual frequencies. In 1964, Anderson developed a method for carrying out a similar process, as he describes in his historical sketch (*Anderson, Weston A.: Early NMR Experiences and Experiments*), with a comb of evenly spaced frequencies generated by a wheel, later termed the 'wheel of fortune'. Before this device could be worked out in detail, however, Anderson seized on a better idea. His notebook of June 3, 1964 shows the concept of using a train of high power rf pulses to accomplish the excitation and a Fourier transform (FT) of the resulting free induction decay (FID) signal to extract the spectrum.

Ernst spearheaded the implementation of this concept. With support from Varian's electronics staff, he put together a pulse spectrometer in two months and by the end of the summer had obtained the first FT spectra. The whole idea was to speed up data acquisition by exciting the entire spectrum at once, recording the FID in the 400 channels of a CAT in about 1 s, then immediately repeating the process to build up S/N. This part worked well, and in an hour over 3000 repetitions could be co-added. However, the process of analyzing the data, as described in Ernst's historical sketch (*Ernst, Richard R.: The Success Story of Fourier Transformation in NMR*), was time consuming and cumbersome, since no on-line computer yet existed. The cartoon in Figure 46, from a historical article by Ray Freeman,²⁷¹ gives a graphic portrayal of the process.

Still, the process did work, and with minicomputers on the horizon the potential for a spectacular advance in NMR technology should have been clear. In fact, the multiplex advantage of using FT methods to obtain a broad frequency range was already well known in infrared spectroscopy (Felgett's advantage), and far-infrared spectra were being obtained routinely by Fourier transformation of the response from a Michelson interferometer. Ernst presented the first FT NMR results at the Experimental NMR Conference in Pittsburgh in February 1965 and drew a mixed response. Some NMR spectroscopists, including those who understood the concept from infrared spectroscopy, appreciated the potential,

Figure 46 The steps involved in processing Ernst and Anderson's early pulse NMR data to obtain Fourier-transformed spectra.²⁷¹ (Reproduced by permission of the American Chemical Society)

while others treated it as an interesting but impractical technique for NMR. Nevertheless, as Ernst says in his article,

We decided to publish the work in the *Journal of Chemical Physics*. However we had no success, the paper was rejected twice, being considered too technical and not of sufficient originality. We then submitted the paper to *Review of Scientific Instruments* on 9 July 1965 where, after further revision, it was finally accepted on 16 September, 1965.²⁷²

Varian management, too, failed to appreciate the potential of the new method and the new generation XL-100 spectrometer appeared in 1969 as a continuous wave instrument, configured in such a way that made the eventual addition of FT hardware cumbersome. Meanwhile, the advantage of multiple NMR suppliers became clear when Bruker pioneered in offering an FT accessory to their HX instruments in 1969, and by 1972 had developed a well-designed FT-only spectrometer. During the 1970s Varian began to catch up, and the other major instrument companies also soon got into the FT arena.

The Critical Role of On-Line Computers and Software

Often timing is everything! Without the increasing availability of minicomputers that could be directly interfaced to the spectrometer, FT NMR would have remained an interesting laboratory curiosity. Small laboratory computers that had begun with the development of the LINC at MIT in the early 1960s were available commercially in 1965. However, as Ernst

relates,²⁷³ it was not until the fall of 1966 that Varian actually purchased such a computer—the PDP-8 from Digital Equipment Co., a programmable computer with a memory of 4096 12-bit words. Even then, priority was given to its use with an A-60 to carry out homogeneity optimization and various types of data processing. Eventually, however, in several laboratories throughout the world these ‘state-of-the-art’ computers began to be interfaced to NMR spectrometers. Coincidentally, in 1965, the same year that Ernst and Anderson’s work was first displayed, J.W. Cooley and J.W. Tukey at Bell Laboratories had developed a new algorithm for carrying out the Fourier transform in a far more efficient way than had ever been available before.²⁷⁴ With this advance, a PDP-8 could carry out a Fourier transform of 4096 data points in ‘only’ 10–20 min. Gradually, the pioneers in FT NMR methods learned how to do phase corrections and how to circumvent the most serious of the artifacts from the experiment and the data processing.

Initially a computer such as a PDP-8 was used to carry out the computations, while data were accumulated in a separate time-averaging computer. The Varian C-1024 was widely used, but gradually gave way in some laboratories to such devices as the Fabritek 1064 which could handle up to 4096 data channels. The first practical computers for on-line FT NMR were the Nicolet 1080, which incorporated the Fabritek technology with a programmable computer, and the Digilab FT NMR accessory, a modification of a Data General computer originally developed for infrared spectroscopy. The dynamic range of the computer was a significant consideration in these early days when computations were limited to fixed point numbers, with Nicolet opting for a 20-bit word while most other manufacturers stayed with the then conventional 16 bits. Each major NMR manufacturer began development of its own special-purpose computer. For example, George Levy, who obtained an early Varian XL-100 that was modified for FT studies, says (Levy, George C.: *Recollections: Computers in the Early Days of ¹³C NMR and 25 Years of Growth in NMR Computing*):

The system computer was a Varian 620i with 16 384 16-bit words of core memory and a paper tape punch/reader on its teletype user I/O device. There was no magnetic storage—disk or tape. Every time we had a glitch or (heavens!) software failure, the computer had to be reloaded by hand toggling a starter program and then loading several paper tapes at 110 baud (about 12 characters per second). The very limited computer memory only allowed minimal NMR data acquisition and processing software, and only a single FID of 8k data points could be acquired and stored. In a few months we added an additional 16 kbyte stack of core memory at about \$0.70 per 16-bit word, over a million times the cost of much smaller and faster modern memory chips.

The practice of NMR companies of using their own, rather specialized computers with proprietary software continued until relatively recently and probably increased costs and delayed the introduction into NMR of the most advanced general-purpose computers. Nevertheless, the NMR industry and all NMR users eventually benefited from the several revolutions in computer technology over the last 30 years. The complex multiple pulse experiments that we discuss in later sections could not have been developed in a practical way without the infrastructure of the computer age.

FT NMR Becomes a Reality

¹³C NMR was the big prize. Proton NMR was established and reasonable sensitivity could be obtained for most organic

chemical studies, but the exploitation of ^{13}C NMR really required the order of magnitude improvement in sensitivity furnished by FT methods. Several laboratories pursued this goal. For example, at the National Bureau of Standards in 1969, Tom Farrar and his colleagues used a Fabritek Model 1064 time-averaging computer with 4096 words of memory to record ^{13}C FIDs and go through a tedious procedure in order to process the data and obtain ^{13}C FT spectra. In his historical sketch (*Farrar, Thomas C.: Historical Reminiscences of Some NMR Experiences*), Farrar says:

FID spectra were output on the punch paper tape and when we had a laundry basket full of tape we would drive 10 miles down the road to NIH to carry out the data reduction. The data reduction at NIH involved several computers since the computer which could read the punched paper tape had no plotter or graphics; it was used to convert the paper tape to punched cards which were then carried to another computer where the Fourier transformation and plotting were done. After a year of this tedious process we convinced Dick Cushing of FabriTek (which later became Nicolet Instruments) to build a very simple computer into the signal averager. My group at NBS purchased model # 1 [Nicolet Model 1080]. It worked beautifully from the first day it was installed and was still working a few years ago.

Meanwhile, also in 1969, at Bruker Instruments, Tony Keller (*Keller, Tony: The Development of the First Multinuclear Fourier NMR Spectrometers*) was able to interface a PDP-8 computer to a Fabritek 1064 and achieve broadband decoupled ^{13}C NMR by pulse excitation followed by on-line processing. Keller reported his results briefly at a meeting of the Society for Applied Spectroscopy at the Disneyland Hotel in Anaheim in late 1969. The difference between the new FT spectra and what had been achieved previously was remarkable. As Keller says in his article,

When the most famous ^{13}C spectroscopist of the CW era stepped into our hospitality suite, he pondered my decoupled ^{13}C spectra hanging on the wall and asked, 'Do you also have ^{13}C data?' It took me a long time to convince him that, in fact, he had ^{13}C spectra before his incredulous eyes.

The Fourier transform revolution had begun. Organic chemists could see the potential of the new methods and eagerly used the FT accessories offered by the instrument companies. Inorganic chemists, too, began to see the possibilities of studying nuclei of low sensitivity or low natural abundance, and multinuclear instruments became more popular. In later sections we shall explore these advances in more detail.

As computers became more efficient, the productivity of NMR laboratories increased. It became possible to obtain a routine ^1H NMR spectrum of a milligram sample of a typical organic compound in a few minutes. FT methods also permitted NMR to be carried out with much smaller amounts of material, thus facilitating the study of samples such as many natural products that were available in only limited amounts. For example, by using microcells containing only about 15 μL of solvent, optimizing instrumental parameters, and carrying out overnight accumulations, it was possible by the mid-1970s to obtain usable ^1H spectra of the type shown in Figure 47 from 1 μg of a steroid and ^{13}C spectra with less than 1 mg. Biochemistry, too, benefited enormously from the sensitivity gains of FT techniques, as we shall see in Section 10.

Chemists were eager to exploit the efficiency and versatility of the new methods, but many approached FT NMR with some trepidation. Instead of familiar ideas such as frequency

Figure 47 FT NMR spectra obtained in overnight scans with 1.7-mm diameter sample tubes. Top: 80 MHz ^1H spectrum of 1.0 μg of cortisone-21-acetate in 15 μL of CDCl_3 . Bottom: 20 MHz ^{13}C spectrum (proton noise decoupled) of 500 μg ethyl vanillin in 7.5 μL of CDCl_3 . (Courtesy of J.N. Shoolery)

sweep, scanning speed, and ringing, they encountered a new vocabulary of 'pulse width', 'aliasing', and ' T_2 ', together with new concepts related to Fourier domains. Help was at hand, however, as new books appeared that were aimed at the chemist. Farrar and Becker's *Pulse and Fourier Transform NMR: Introduction to Theory and Methods*²⁷⁵ was published in 1971 and helped explain the world of pulses. About five years later Derek Shaw's *Fourier Transform NMR Spectroscopy*²⁷⁶ and Müllen and Pregosin's *Fourier Transform NMR Techniques: A Practical Approach*²⁷⁷ gave further welcome guidance. Meanwhile in 1972, Levy and Nelson's *Carbon-13 Nuclear Magnetic Resonance for Organic Chemists*²⁷⁸ provided examples of the practical value of FT methods, not only in acquiring spectra but in studying dynamic processes.

Time-Dependent Processes with Multiline Spectra

Prior to the onset of FT methods, rf pulses had been used extensively, as we saw in Section 4, to study NMR relaxation, molecular diffusion, and reaction kinetics, but almost entirely in systems with one major NMR line. With FT methods it soon

became possible to adapt many of these pulse sequences to multiline spectra. The short paper by Vold et al.,²⁷⁹ illustrated in Figure 49, showed the advantages of the FT approach in measuring T_1 . Bob Vold (**Vold, Robert L.: Reflections**) describes the origin of this work in an informal evening discussion at a meeting in the summer of 1967:

We thought for a while that with just two pulses, spin-lattice relaxation AFTER the second pulse would distort the signal beyond recognition. Soon we saw the error in this argument, and realized that if the first pulse were an inversion pulse one could by means of FT measure the T_1 of each line in the spectrum. John Waugh realized the implication of this invention and convinced Melvin Klein (who at Berkeley had one of the few working FT systems) to try the experiment. My main

contribution to the resulting paper was the suggestion that a field-gradient pulse, applied between the inversion and detection pulse to destroy unwanted coherence, could also be used in a Fourier transform spin echo sequence to measure diffusion coefficients of individual chemical species.

'Partially relaxed' spectra became common as FT instruments were more widely available. For example, Laurie Hall (**Hall, Laurance D.: NMR Studies of Carbohydrates**) found that T_1 values provided information on the conformation of sugars, since proton relaxation occurred by an intramolecular dipole-dipole mechanism.^{280,281} George Levy and co-workers did extensive inversion-recovery studies of ^{13}C to learn about anisotropic tumbling and internal molecular motions,^{282,283}

The FOURIER TRANSFORM

Jean Baptiste Joseph Fourier, (Figure 48), born in 1768, had a varied career as a diplomat, administrator under Napoleon, engineer, and research scientist, as described in more detail by Derek Shaw in his book *Fourier Transform NMR Spectroscopy*.²⁷⁶ Fourier's ideas on using a series of trigonometric functions to represent a general mathematical function arose while he was in Egypt as a diplomat during the end of the 18th century. The concept of the Fourier series and later of the continuous analog, the Fourier transform, were developed in papers in 1807 and 1810, and expanded in 1822 in his book *Théorie Analytique de Chaleur* (Analytical Theory of Heat).

The value of Fourier transformation to extract fundamental frequencies from a function varying in time was well understood by physicists and engineers. However, the calculation of numerical Fourier transforms by 'brute

force' summations was difficult and very time-consuming in digital computers until the development of the 'fast Fourier transform' algorithm by Cooley and Tukey in 1965.²⁷⁴ The new method substituted additions for multiplications and reduced the number of steps for transforming N data points from essentially N^2 to $N \log_2 N$ — a very significant reduction for N in the thousands.

Not surprisingly, similar efforts to develop new computer approaches were underway elsewhere in the same time frame. For example, Yoji Arata in his historical sketch (*Early Days of NMR in Japan*) comments on an FFT algorithm prepared at the University of Tokyo in the mid-1960s. Subsequently, many refinements in FFT programs have been adopted, and more recently alternative techniques to the Fourier transform have been developed for efficient extraction of spectral information from time responses and optimization of signal-to-noise ratios.

while Allerhand, Doddrell, and Komoroski found that ^{13}C T_1 values for protonated carbons in moderate size molecules such as steroids were often fractions of a second, rather than the tens of seconds that had been forecast.²⁸⁴ These fundamental findings provided the data needed for the efficient study of a wide range of organic molecules in order to elucidate structure and conformation.

Forays were made into the use of NMR to measure diffusion, flow, and exchange processes in systems that had been intractable when only single-line spectra could be readily studied. For example, James and McDonald²⁸⁵ measured self-diffusion coefficients in a solution of dimethyl sulfoxide in water.

Further Advances in FT Methods

Early FT spectrometers relied, as did their continuous wave counterparts, on a single phase-sensitive detector and the exciting pulse had to be set at a frequency that was off to one side of the entire spectrum. It soon became apparent that this procedure wasted half the pulse power (which was always at a premium) and decreased S/N by $\sqrt{2}$ from noise folded over into the observed frequency range. One solution is to use two phase-sensitive detectors with their reference signals out of phase by 90° , a quadrature phase detection (QPD), or alternatively, as shown by Redfield and Kunz,²⁸⁶ to increment the phase of one detector by 90° after each successive pulse. The problem encountered with the implementation of QPD (or the Redfield alternative) was that imperfections in hardware and unavoidable variations in phase caused small, unwanted peaks (quadrature images). Considerable effort went into overcoming this problem, with the most successful method being that developed by David Hoult (*Hoult, D. I., Biomedical NMR Instrumentation—A Personal Viewpoint*) in Rex Richards's laboratory at Oxford. The solution is to permute phases and add or subtract the responses to four successive pulses in a 'CYCLically Ordered Phase Sequence'. The CYCLOPS method²⁸⁷ or some variant²⁸⁸ has been employed on almost all NMR spectrometers since the mid-1970s. Moreover, the concept of phase cycling has become an

indispensable part of modern two-dimensional and multiple quantum NMR methods, as we shall see in Section 11.

Most Fourier transform NMR spectra are obtained using short rf excitation pulses, but other broadband methods of excitation have been utilized with varying degrees of success. The use of 'stochastic excitation', in which pseudorandom noise is used to excite all frequencies over a particular range, was conceived by Russell Varian in a little-known patent, but was rediscovered and introduced in concurrent papers by Ernst²⁸⁹ and Kaiser²⁹⁰ in 1970. Correlation of the output, which is no longer quite random noise, with the input noise and Fourier transformation produces a spectrum. Tomlinson and Hill²⁹¹ carried this process a step further by generating the input 'noise' with a frequency spectrum that is flat except for a 'notch' at the frequency or frequencies that one does *not* wish to excite, such as solvent resonances. These stochastic excitation methods have been improved and are found to be useful in a number of instances, but have never achieved the popularity of the more versatile pulse techniques.

In 1974, Dadok and Sprecher²⁹² proposed a continuous wave excitation in which the magnetic field or frequency is swept so rapidly that transient effects ('wiggles') dominate the spectrum. They showed that this spectral response can be converted to the ideal slow passage spectrum by a cross correlation with a single line obtained under the same rapid scan condition. With some improvements and limitations suggested in papers by Gupta, Ferretti, and Becker²⁹³ and by Ferretti and Ernst,²⁹⁴ this rapid scan correlation method served as a useful adjunct to pulse techniques and was exploited in a number of applications, especially those in which a strong solvent signal must be avoided. It has been adopted commercially by Hitachi for routine, low-field spectrometers. While technically not requiring transformation between two Fourier domains, the cross correlation can, in practice, usually be carried out most efficiently by two consecutive Fourier transform steps.

A Pulse Sequence for Almost Every Purpose

While the greatest virtue in pulse FT methods lies in the rapid broadband excitation of an entire spectrum, there has been an increasing need to retain the versatility of pulse methods while restricting the frequency range over which the rf is effective in exciting nuclear spins. Redfield introduced a 'long' pulse positioned in such a way as to excite a range of frequencies without exciting one particular frequency (usually that of solvent water)²⁹⁵ and later improved this with a composite of several pulses applied in succession (the '2-1-4 technique'),²⁹⁶ which served as the prototype for a large number of further composite sequences.

The converse method using a series of short, high-power pulses to achieve excitation over only essentially a single frequency was developed by Gareth Morris in 1976 while he was an undergraduate doing a research project with Ray Freeman. In his article (*Morris, Gareth A.: The Origins of DANTE*) he describes the thought processes that led to the idea of applying a series of short pulses with intervals in which all nuclei not exactly on resonance dephase are not effectively excited by subsequent pulses. The method worked well. As Morris puts it,

The most difficult part of the whole exercise was agreeing to a suitably pithy name for the experiment. I had been reading

the *Divine Comedy* (in translation, after a brief and unequal struggle with Dante's Italian) and had been struck by the parallel between the path taken by Dante and his guide Virgil through Purgatory and the trajectories of nuclear magnetizations during our experiments ... so we settled on the acronym DANTE (*Delays Alternating with Nutations for Tailored Excitation*).

A very large number of other specialized pulse sequences have been developed as NMR spectroscopists learned how to tailor excitations to achieve wide-ranging objectives. For example, the idea of using a composite pulse has developed well beyond the original use by Redfield to encompass pulses designed to correct for B_1 inhomogeneity and resonance offset effects.²⁹⁷ Levitt and Freeman (*Levitt, Malcolm H.: A Cyclic Evolution In Spin Space*) went on to combine such composite pulses into cycles and 'supercycles', appropriately named by Freeman MLEV-4, MLEV-16, etc.,²⁴⁹ that could serve as an effective means of broadband decoupling. Freeman's historical sketch reviews the history of decoupling and shows how this conception of the decoupling process, together with a novel theoretical development by John Waugh (*Waugh, John S.: Alchemy of Nuclear Spins*), completely changed the experimental approach from the idea of noise modulated decoupling, a method that had been in use for 15 years. Subsequently, such pulse sequences as WALTZ (based on a 90°, 180°, 270° sequence of relative lengths 1-2-3) and its successors have dominated all broadband decoupling experiments and are widely implemented in all commercial spectrometers.

An important pulse sequence developed by Morris and Freeman²⁹⁸ in 1978 and named INEPT (*Insensitive Nuclei Enhanced by Polarization Transfer*) has proved to be a durable method in its own right and later, as we shall see, as a component in several complex multidimensional NMR experiments. The INEPT sequence of 90° and 180° pulses is designed to create a population inversion among the sensitive spins (such as ^1H) which then results in polarization being transferred to the less sensitive spins (such as ^{13}C) to enhance their signal by the ratio $\gamma_{\text{H}}/\gamma_{\text{C}}$. In addition to sensitivity enhancement, INEPT and its later modifications discriminate among carbon nuclei bonded to zero, one, two, or three hydrogen atoms, and hence can serve as a means of 'editing' a complex spectrum and aiding in its assignment.

The success and the limitations of INEPT stimulated other sequences such as DEPT (*Distortionless Enhancement of NMR Signals by Polarization Transfer*), developed by Doddrell, Pegg, and Bendall,²⁹⁹ as described by Doddrell (*Doddrell, David M.: An Historical Perspective of Research Based Upon Misguided Advice*). DEPT has the same goal as INEPT but is designed for a broader range of applicability and, as its name implies, to avoid the distortions that can occur in INEPT spectra.

An alternative technique, APT (*Attached Proton Test*), was introduced by Patt and Shoolery in 1982 specifically for editing ^{13}C spectra.³⁰⁰ APT is based on the modulation of a spin echo introduced by ^{13}C -H coupling if decoupling is turned off between the initial 90° and 180° pulses and then turned on for the rest of the experiment. APT lacks the polarization enhancement advantage of INEPT and DEPT, but retains the intensity improvement often found from the nuclear Overhauser effect in ^{13}C NMR.

A rather different type of pulse sequence (given the acronym INADEQUATE) was developed in 1980 by the Freeman

group³⁰¹ to permit the observation of one-bond ^{13}C - ^{13}C spin coupling, even though at natural abundance only about one molecule in 10 000 possesses adjacent ^{13}C atoms. To discriminate against unwanted signals from ^{12}C -containing molecules, the phases of the four pulses in the sequence as well as the acquisition are cycled. Together with the CYCLOPS cycling needed for suppression of quadrature artifacts, 128 steps are thus used for INADEQUATE. As Ad Bax says in his historical sketch (*Bax, Ad: NMR of Ethanol and Interferon- γ*) 'Unfortunately, our complex phase cycle led to the idea: "the more phase cycling the better—no questions asked" '.

Dozens of other pulse sequences, many bearing acronyms designed to ensure their place in history, have been developed and contribute immeasurably to the richness and versatility of NMR methods. With the Fourier transform relations to permit the unraveling of the complex time responses from pulse experiments, physicists and chemists were finally given free rein to manipulate nuclear magnetizations and achieve unprecedented results. The era of 'spin gymnastics' had begun. It would bring revolutionary developments to the investigation of NMR in solids, permit nuclei other than hydrogen to be exploited readily, and allow difficult problems in biochemistry and biology to be addressed by NMR.

HIGH-RESOLUTION NMR IN SOLIDS

The history of solid state NMR started with the discovery of NMR itself by Purcell, Torrey, and Pound, who studied solid paraffin in their pioneering experiment. During the early days of NMR, solid state NMR was at least as popular as studies in the liquid state, since the relatively inhomogeneous magnets then available could provide a faithful representation of the inherently broad NMR lines in solids but not the narrow lines known to exist in liquids. The discovery of the chemical shift and the widespread recognition of the importance of this tool for the elucidation of chemical structure put a premium on liquid state studies, since only there were lines sharp enough to reveal this information.

The interaction Hamiltonian in the liquid state corresponds to isotropic chemical shift and scalar spin-spin interactions only, resulting in sharp lines in the spectra and providing the parameters of utmost importance in structural chemistry. In the solid state, on the other hand, anisotropic interactions, such as chemical shift anisotropy, dipole-dipole interactions, and quadrupolar interactions, are all retained in addition to the isotropic chemical shifts and indirect spin-spin couplings. Moreover, the chemical shift anisotropy and the dipolar and quadrupolar interactions usually dominate the spectrum, resulting in broad lines in the solid state. The information carried by the indirect spin-spin couplings and the chemical shifts is consequently 'buried' under the broad and structureless spectral patterns.

As we saw in Sections 2 and 4, many important early applications of NMR had concentrated on the extraction of internuclear distances and orientations from analyses of the usually dominant dipolar interactions. In addition, since the onset of molecular motion by any means could narrow the lines or change the shape of the lines providing a novel method for the study of molecular motions and phase transitions, NMR became a valuable tool for polymer scientists. Spectra of metals and alloys were extensively employed to study Knight

shifts. With the knowledge, however, that spectra in the solid state inherently contain more information than those in the liquid state, many NMR physicists continued to seek methods to obtain spectra with sharp lines, either by eliminating some of the unwanted interactions or by reducing their dominance.

Magic Angle Sample Spinning

As we saw in Section 4, Raymond Andrew first thought about spinning NMR samples in order to resolve the NMR paradox concerning observed line narrowing in the face of a theoretically constant second moment. He and his colleagues developed a method for spinning a solid sample about an axis inclined at an angle of $54^\circ 44'$ to B_0 .¹⁵⁴ These results were reported at the AMPERE Meeting in Pisa in 1960. Gorter found the removal of dipolar broadening quite remarkable and referred to it as 'magic' and the technique was henceforth called 'magic angle spinning'.

Meanwhile, at Washington University, Irving Lowe was studying solids by pulse methods. He and Norberg had already demonstrated that a FID following a 90° pulse could be Fourier transformed to obtain the spectrum.¹³⁶ Lowe speculated that rotating a sample should produce sharp sidebands at frequencies related to the spinning speed. He recognized from the expression for the dipolar Hamiltonian that at the angle of $54^\circ 44'$ the leading term vanishes and sidebands should appear at multiples of the spinning speed. After initial unsuccessful attempts to construct a mechanical device to carry out the rotation, Lowe hit on a different method, as he describes in his historical sketch (*Lowe, Irving J.: My Life in the Rotating Frame*):

About then, I was having some dental work done and saw a new air turbine drill that my dentist used. I decided to try to spin the sample by blowing air past it. A gifted machinist (Jim Boyle) and I made up some NMR samples that were cylinders 7 mm wide, 7 mm in diameter, had nylon bearings and spun on thin phosphor bronze wires as axles. I found that spinning speeds were limited only by the strength of the sample and that speeds up to 7 kHz were easily obtainable. I put the spinner into my NMR probe, found that I could narrow the line of both Teflon and CaF_2 and was so excited that I worked for the next 48 hours taking data, stopping only when I had spun all my prepared samples to destruction.

Lowe's results were published in *Physical Review Letters* in 1959.¹⁵⁵ Data for polycrystalline calcium fluoride are shown in Figure 50 for a spinning axis oriented at $\alpha = 0^\circ$, $54^\circ 44'$, and 90° relative to the magnetic field. CaF_2 was a particularly suitable sample for demonstrating the effects since the F-F distance is large enough to reduce dipolar interactions, and the fluorines form a simple cubic lattice so that chemical shift anisotropy is absent.

Subsequently, Andrew and his co-workers demonstrated in 1962 that high-speed rotation about the 'magic' axis removes spectral broadening arising from anisotropy of chemical shifts in polycrystalline or amorphous specimens,³⁰² and they showed the effectiveness of the high speed magic angle rotation in eliminating spectral broadening arising from anisotropy of symmetric electron-coupled nuclear spin interactions.³⁰³ Examples of chemical shift fine structure resolved in solids by this technique were provided by Andrew and Wynn³⁰⁴ and by Kessemeier and Norberg,³⁰⁵ while the first spin multiplets were resolved in the spectra of solids by

Figure 50 Free induction decays and corresponding FT spectra for polycrystalline CaF_2 as a function of the direction of the spinning axis.¹⁵⁵ (Reproduced by permission of the American Physical Society)

Figure 51 ^{19}F derivative spectra of polycrystalline KAsF_6 . (a) Nonspinning; (b) magic angle spinning at 5.5 kHz.³⁰⁶ (Reproduced by permission of the American Physical Society)

Andrew et al.³⁰⁶ The ^{19}F spectrum of KAsF_6 , shown in Figure 51, has a width for the nonspinning sample of 13.2 kHz, but the 905 Hz splitting arising from the indirect ^{75}As - ^{19}F coupling could be easily resolved in the spectrum of the sample spinning at the magic angle at a rotation frequency of 5.5 kHz.

After this initial burst of activity which established the validity of the method, physicists largely turned to other studies and magic angle spinning was little used and was largely unknown to the chemists who might have applied

the method to interesting problems. By 1970, however, Doskočilová and Schneider in Prague had constructed a magic angle spinner and demonstrated line narrowing in ^1H NMR, which they later applied to polyethylene (see *Doskočilová, Danica & Schneider, Bohdan: Development of Magic Angle Rotation for the Narrowing of Proton NMR Lines in Organic Materials*). Also, their study of ion-exchange resins in 1972 showed that inhomogeneities from magnetic susceptibility variations in a mixed solid/liquid sample could be largely eliminated by MAS.³⁰⁷

The widespread revival of MAS began largely with the work of Jacob Schaefer and Edward Stejskal, then at the Monsanto Chemical Company, who were investigating ^{13}C NMR at natural abundance in polymers with the FT methods that had recently become available commercially. As Schaefer points out in his article (*Schaefer, Jacob: A Brief History of the Combination of Cross Polarization and Magic Angle Spinning*), he was frustrated in trying to obtain data in solution from polymers that were only partially soluble. In a visit to nearby Washington University, he recounted these problems to Samuel I. Weissman, a pioneer in the development of electron spin resonance:

Sam suggested forgetting about solvents and using magic angle spinning on the solid polymers instead. I objected that I didn't want to get involved in an experiment which was both difficult and dangerous. (I recalled a magic angle spinning talk featuring a slide showing the operator at a console separated from the magnet gap by a wall of sandbags!) Sam led me into his office, reached up to a book shelf, and took down a cigar box from behind a pile of journals. Within a few minutes he had assembled a magic angle spinning device consisting of a solid Lowe rotor suspended on two L-shape bronze wires. The short ends of the wires fit into tiny holes machined into the center of each end of the rotor. The long ends of the wires were held by spacers and Teflon tape to the sides of a glass pipette. The tip of the pipette was aimed at flutes which had been cut around the barrel of the rotor. Sam gave a gentle puff and the rotor whistled into action: magic angle spinning and no sandbags.

Schaefer immediately adapted the Lowe spinner to his probe, used a cardboard protractor to adjust the magic angle, set the spinning speed by the pitch of the sound that was emitted, and found that the apparatus worked to narrow the ^{13}C linewidth in a sample of rubber by a factor of two. Schaefer and Stejskal improved the apparatus, learned how to make better rotors by machining solid polymers, and constructed a rotor for enclosing other samples. Their talks and publications stimulated other chemists to try MAS, but the real growth in the use of MAS would come only when commercial probes became available in 1978 and when this technique was combined with other elegant pulse methods, as we describe in following sections.

Two other aspects, namely the setting of the magic angle and the rotor designs, are important for an efficient magic angle spinning experiment. For maximum resolution, the angle between the spinning axis and the magnetic field direction must be as close to the magic angle as possible since imprecise settings produce line broadening. Frey and Maciel³⁰⁸ developed procedures for measurement of the ^{13}C NMR linewidths in standard samples, such as hexamethylbenzene, or the use of quadrupolar nuclei, such as ^{81}Br in KBr. Bodenhausen et al.³⁰⁹ suggested the use of a laser beam to align the angle optically. A simple and accurate procedure for setting the magic angle using line separations instead of

linewidths in the ^{13}C spectra of molecules such as chloroform oriented in the nematic phase of liquid crystals was proposed and utilized by Khetrapal et al.³¹⁰ in 1987.

The rapid growth of magic angle spinning experiments is the result of a variety of modifications in the rotor materials and design. David Doty in his article (*Doty, F. David: A Random Walk Toward High-Speed Sample Spinning*) describes the steps needed to develop MAS probes commercially, and Hans Jakobsen's article (*Jakobsen, Hans J.: A Retrospect on the Development of High-Speed Sample Spinners for Solids since 1980*) recounts some of the improvements in his laboratory and in Gary Maciel's laboratory as they competed to reach supersonic rotation speeds. The rotor materials must be nonconducting and mechanically stable to sustain high rotation speeds. As far as possible, they should not contain the material to be investigated. Boron nitride, Kel-F, Macor, and Delrin have been commonly employed. Before the 1980s, most spinners were based on modifications of Andrew's design employing a conical surface with a single air bearing and drive source. However, cylindrical rotors with separate bearing and drive systems also emerged and the maximum spinning speed generally permitted was 4–5 kHz. There have been gradual improvements in the rotor designs resulting in a considerable increase in spinning speeds. Recently, spinning speeds up to 26 kHz for a 3.5 mm rotor have been achieved.

Magic angle spinning experiments have been widely used to study many solids, polymers, liquid crystals, metals, proteins, biological membranes, and numerous other materials. Not only have the lines been narrowed so as to obtain fine structure due to indirect spin–spin couplings and chemical shifts, but the intensities of spinning sidebands have been employed to derive information which is not otherwise easy to obtain. Lippmaa et al.³¹¹ and Stejskal et al.³¹² reported independently that spinning the sample at the magic angle with a rotation speed lower than the frequency spread of the shielding anisotropy profile yields a sharp peak at the isotropic chemical shift value, along with a series of equally sharp sidebands separated by the spinning frequency, and the intensities of the sidebands reflect the profile of the chemical shielding anisotropy. Lippmaa showed that the intensities of the first sidebands could be related to the anisotropy pattern for the axially symmetric shielding tensor. A general procedure to correlate the anisotropy pattern with the intensities of the individual sidebands was described in terms of general integral and series expansions by Herzfeld et al.,^{313,314} while Arun Kumar et al.³¹⁵ utilized the relative intensities of the spinning sidebands for the determination of the signs of the dipole- and quadrupole-split doublets in the spectra of oriented molecules spinning at the magic angle.

The technique of 'off' magic angle spinning has also been employed instead of 'on' magic angle spinning to derive useful information. In such cases the lineshape of the powder pattern is retained for all angles, while the overall linewidth is governed by the factor $3 \cos^2\alpha - 1$, where α is the angle between the spinning axis and the magnetic field. Near magic angle spinning experiments in oriented systems in order to reduce strongly coupled spectra to weakly coupled ones were performed by Courtieu et al.³¹⁶ in 1982.

Rotating Magnetic Fields at the Magic Angle

Many of the applications of high-resolution NMR need much higher spinning speeds than are easily available in order to average out anisotropic interactions and produce the desired line narrowing. In order to avoid such problems of very high speed mechanical rotation, Andrew and Eades³⁰² in 1962 proposed an alternative approach. The idea is simple. It is the motion of the nuclei relative to their magnetic environments that causes the line narrowing and this can be achieved either by motion of nuclei in a static magnetic field or by placing the static sample containing the nuclei in a magnetic field which is rotating. The requirement in such an experiment is a stable and uniform strong magnetic field rotating at a frequency of the order of 50 kHz with the magnetic field vector inclined at an angle of $54^\circ 44'$ to the axis of rotation. This can be achieved by a superposition of fields applied along three mutually orthogonal directions: a steady field along the z direction and two alternating fields along the x and y directions with their phases in quadrature. The feasibility of this technique was demonstrated with the observation of electron paramagnetic resonance in a free radical³¹⁷ and of NMR in liquid paraffin,³¹⁸ both in very low magnetic fields. However, the difficulty of generating a sufficiently large and uniform rotating magnetic field precluded the development of this intriguing approach into a practical experimental procedure.

Meanwhile, alternative methods based on pulse techniques and phase-sensitive detection were underway at the University of Pittsburgh, where both Lee and Goldburg^{319,320} and Barnaal and Lowe³²¹ independently reported line-narrowing pulse methods in solids in which the rf fields are rotated instead of the samples. They showed that in the rotating frame the effective Hamiltonian has time-independent terms that are the same as the static Hamiltonian but multiplied by a factor $\frac{1}{2}(3 \cos^2 \alpha - 1)$. For $\alpha = 90^\circ$, the factor becomes $-\frac{1}{2}$ so the FID should evolve half as fast, as shown by Barnaal and Lowe. Lee and Goldburg used the magic angle where the dipolar Hamiltonian vanishes. This method is in many respects equivalent to the observation of a free induction decay in a rotating sample, but the line-broadening associated with anisotropic chemical shifts in polycrystalline materials is not removed in such experiments. Although it did not lead to very high resolution in solids, a lengthened decay corresponding to narrowed NMR lines was observed. In practice, it was difficult to generate a sufficiently uniform strong rf field to ensure that the effective field is directed at the magic angle for all parts of the sample.

Removal of Homonuclear Dipolar Interactions by Multiple Pulse Techniques

The Lee–Goldburg experiment was influential in demonstrating that rf pulse sequences could be used to manipulate nuclear spins into responding to a Hamiltonian that is controlled, at least partially, by the experimenter. To some extent, such investigations had had their origins in Hahn's spin echo and the subsequent Carr–Purcell and Meiboom–Gill techniques. The latter experiment was probably the first to take advantage of not only the timing of pulses, but their relative phases. In 1962, Powles and Mansfield had extended the

Figure 52 Train of ^{19}F echoes in powdered $\text{Co}(\text{NH}_3)_6 \cdot (\text{BF}_4)_3$, which has a T_2 value of $\sim 45 \mu\text{s}$. The decay shown covers about 10 ms.³²² (Reproduced by permission of the American Physical Society)

concept of reversing certain spontaneous effects of the Hamiltonian by showing that the decay of magnetization due to dipolar interactions in a solid can be refocused by applying a second 90° pulse that is 90° out of phase with the initial pulse.

All these observations indicated the prospects of observing useful effects as a result of applying more complex pulse sequences. However, in most early pulse spectrometers, pulses were produced by gating electrode voltages on free-running rf oscillators, so that the rf phase of one pulse was unrelated to that of the following or the preceding pulse. In spite of the success of the Meiboom–Gill and Powles–Mansfield techniques, considerable electronic technology had to be developed to permit the incorporation of relatively long and complicated pulse trains coupled with high-power transmitters, all subject to control of phase, with phase-sensitive detection.

A new company formed by the merger of Harvey Wells and Magnion, under the guidance of Edward Ostroff, began to develop a line of pulse NMR spectrometers offering the desired capabilities. John Waugh, who served as a consultant to Magnion, describes some surprising results (*Waugh, John S.: Alchemy of Nuclear Spins*):

Testing an early machine in the spring of 1965, Ostroff chanced to apply a Carr–Purcell (CPMG) sequence to a solid, and was astonished to see a long train of echoes—up to thousands of them as the pulse spacing τ was decreased. I was equally surprised, but as the consultant I was supposed to explain the effect.

Ostroff and Waugh³²² found that the echoes were optimized for a train of 90° pulses and that solids having T_2 values in the range of tens of microseconds produced echoes lasting as long as 10 ms, as illustrated in Figure 52. Waugh concluded that the known solid-echo¹³⁹ could account for the first echo in the train, and developed a rough theory to account for the remaining train, a theory that was later refined and published by Waugh and Wang³²³ in 1967.

At Nottingham University in the UK, Peter Mansfield was also exploring the effect of a train of 90° pulses and observed a similar effect as an effective lengthening of the FID in calcium fluoride, and Mansfield and Ware³²⁴ reported the effect in 1966 shortly after the Ostroff–Waugh paper had appeared. Thus began a long competition between these laboratories, which was soon joined by Bob Vaughan and his colleagues at Caltech (See *Gerstein, B. C.: The Vaughan Days, CRAMPS, and Transient Techniques in NMR and Dybowski, Cecil: Bob Vaughan and Solid State NMR at Caltech in the 1970s*).

While the theory of multiple pulse studies and several successively improved pulse sequences were developed in all three laboratories, the underlying principles were illuminated primarily by Waugh and his colleagues in terms of Average Hamiltonian Theory. He gradually developed the basic insights

Figure 53 ^{19}F free induction decays for a mixture of solid CaF_2 and liquid $\text{C}_6\text{H}_5\text{CF}_3$, together with their Fourier transforms. Top: 90° pulse. Bottom: application of four-pulse WAHUHA sequence.³²⁶ (Reproduced by permission of the American Physical Society)

Figure 54 ^{19}F spectra of solid C_6F_{12} obtained by Fourier transformation of (a) the FID following a 90° pulse and (b) the response to a four-pulse WAHUHA sequence.³²⁷ (Reproduced by permission of the American Chemical Society)

into the behavior of a spin system subjected to a cyclic pulse sequence and sampled at particular time intervals. However, as Waugh says,

The goal remained to design a pulse sequence that would remove dipole–dipole couplings and retain chemical shifts. In hindsight this should have been easy, but in fact I had no idea whether it was even possible. Suddenly one fall morning at breakfast the solution came to me in a rush. Within a few minutes the WAHUHA sequence, ... its scaling factor and timing variants, its relationship to the magic angle and the Lee–Goldburg experiment, etc., were all obvious.

Waugh and his co-workers published the basic ideas of a four-pulse sequence,³²⁵ and with the arrival of Ulrich Haeberlen from Germany the theory was further refined

and experimentally tested. He, along with Lee Huber who was already in Waugh's laboratory, modified an old Varian spectrometer for the new sequences. The spectrometer was capable of firing 90° pulses in rapid succession on a timescale of the decay time T_2 of the FID of a solid, i.e. $20\text{--}30\ \mu\text{s}$. Within T_2 , four pulses with mutually orthogonal rf phases and spaced by delays $\tau\text{--}2\tau\text{--}\tau\text{--}2\tau$ had to be applied, and the NMR response acquired between the pulses. These were stringent requirements that could be met only with great difficulty.

The first experiment was performed on the ^{19}F resonance of a sample consisting of a small chip of a single crystal of CaF_2 and some liquid $\text{C}_6\text{H}_5\text{CF}_3$.³²⁶ Figure 53 shows the results from the oscilloscope traces. The ordinary FID shows a fast decay of the solid signal, followed by a much longer decay of the liquid signal. Application of the four-pulse sequence $[-\tau\text{--}90^\circ_x\text{--}2\tau\text{--}90^\circ_{-x}\text{--}\tau\text{--}90^\circ_y\text{--}2\tau\text{--}90^\circ_{-y}]$, with $\tau = 6\ \mu\text{s}$, resulted in a signal for the solid that was comparable in decay time with that of the liquid. The Fourier transforms showed that the sequence was able to resolve chemical shifts (scaled down by a factor of $1/\sqrt{3}$). The pulse sequence was referred to as WAHUHA after WAugh, HUber, and HAEberlen. The net effect of the sequence on the magnetization is easily visualized and can be considered as equivalent to the spin spending equal times (2τ) along the x , y , and z axes, which produces the same average behavior as alignment along the magic angle axis.

Figure 54 shows a true 'high-resolution' ^{19}F spectrum of C_6F_{12} obtained with such a four-pulse WAHUHA sequence (with a cycle time of $21\ \mu\text{s}$ and a 90° pulse width of $1.1\ \mu\text{s}$) in comparison with an ordinary NMR spectrum in the solid state.³²⁷ The suppression of the dipolar broadening reveals the AB quartet, reflecting the presence of the distinguishable interacting axial and equatorial fluorines. Although this provided a potentially very powerful technique in the solid state, the real exploitation occurred much later

Figure 55 Sketch of the compensated reflection symmetry of the MREV-8 cycle.³³⁵ (Reproduced by permission of the Royal Society)

due to the extreme demands on instrumentation. The historical sketches by Michael Mehring (*Mehring, Michael: Advent and Evolution of High-Resolution NMR in Solids: A Personal View*) and Ulrich Haeberlen (*Haeberlen, Ulrich: The Early Days of Multiple Pulse NMR*) provide additional insights into the course of these developments. As Haeberlen points out,

The unique *something* which the [multiple pulse] line-narrowing method promised to make amenable to measurement—and eventually did—was the shielding tensor of protons and ^{19}F nuclei. This was clear to us from the very beginning, but it took us almost a full year before at last we could record a [multiple pulse] spectrum from a solid with two separate resonances, and with one of them displaying even a feature which the loving eye could recognize as a chemical shift anisotropy powder pattern.

The first measurement of the chemical shielding tensor for ^{19}F was reported by Mehring et al.³²⁸ in 1970 in fluoranil, and publication of high-resolution ^1H spectra^{329,330} came in 1973.

The WAHUHA cycle does not correct for rf inhomogeneity effects, and it is this inhomogeneity that limits the resolution of these experiments. Various other more complex pulse schemes using the principles of the four-pulse WAHUHA sequence as the basic building combination were subsequently developed in order to improve performance. One such modification, first shown theoretically by Mansfield^{331,332} in 1970–71 and subsequently verified experimentally by Mansfield et al.³³³ and also by Rhim, Elleman, and Vaughan³³⁴ in 1973, is an eight-pulse cycle named MREV-8 to reflect its inventors and the number of pulses. The procedure is to follow one reflection symmetry cycle by a second in which the rf carrier phases of, say, the x pulses only are reversed as shown in Figure 55.³³⁵ MREV-8 continues to be used along with various modifications. A 24-pulse sequence BR-24, introduced by Burum and Rhim³³⁶ in 1979, has become one of the standard multiple pulse sequences. Blinc and co-workers³³⁷ developed multiple pulse sequences in combination with gradient pulses to study diffusion in solids. By this method slow diffusion is measurable in solids in a direct fashion.

With the development of improved instruments, including the incorporation of minicomputers in commercial NMR

spectrometers, established multiple pulse sequences could better be used for applications to chemical problems, especially in the field of polymers. However, the complexity of the methods and their sensitivity to changes in instrumental parameters delayed their widespread use. As Richard Ernst has pointed out, ‘... we spend 70% time on solids but get 70% of the publications on liquids ...’

Work on polymers using multiple pulses provided a wealth of information on their structure and motion, information which otherwise could not be derived easily with reasonable certainty. Teflon was the first polymer investigated by this technique during 1969–71.^{338,339} Subsequently, Garroway, Stalker, and Mansfield³⁴⁰ illustrated that information on orientational ordering and molecular motion in different phases of Teflon can also be obtained from such experiments. Vega and English³⁴¹ combined chemical shift information with relaxation data to study the detailed molecular motion in Teflon, while Dybowski and Vaughan³⁴² studied anisotropic lattice motions in natural rubber and *cis*-polyisoprene. Rhim and co-workers^{343,344} employed multiple pulse NMR in spin-temperature experiments, such as spin-locking and adiabatic demagnetization in the rotating frame. Multiple pulse methods were beginning to have practical application.

The Hartmann–Hahn Concept

In a system containing ‘dilute’ spins such as ^{13}C or ^{15}N at natural abundance, homonuclear dipolar couplings normally do not show up due to low natural abundance and the heteronuclear dipolar couplings with ‘abundant’ nuclei such as protons can in principle be eliminated by decoupling experiments, provided adequate continuous wave power is available at the sample. As electronics improved, it became possible to obtain high-resolution spectra in these systems. However, the signals in such cases are rather weak, in general, because of the low natural abundance, small magnetic moment, and long spin–lattice relaxation time of the dilute nucleus. A gain in the sensitivity can be achieved by utilizing the magnetization reservoir of the abundant systems.

A clever means for efficiently transferring polarization from one nuclear species to another, even though their precession frequencies are quite different, was suggested by Sven Hartmann and Erwin Hahn in 1960, and two years later they published a detailed explanation and a demonstration of the effect.^{345,346} By drawing heavily on the concept of spin temperature in the rotating frame (see Section 4.2), they showed that two nuclear species of spin I and S with magnetogyric ratios γ_I and γ_S act as though they are strongly coupled when they are acted upon by rotating fields $(\mathbf{H}_1)_I$ and $(\mathbf{H}_1)_S$ tuned to the respective resonances, provided the amplitudes of these rotating fields obey the relation $\gamma_I(\mathbf{H}_1)_I = \gamma_S(\mathbf{H}_1)_S$, called the ‘Hartmann–Hahn condition’. Even though their precession frequencies in the static field $\mathbf{H}_0$ are widely apart, strong coupling occurs via the dipolar interaction between the I and S spins and they can exchange magnetization via mutual spin flips. An application of a nonadiabatic perturbation only to the rare spins may result in a sizeable change in the abundant spin magnetization if the abundant spin relaxation time is long compared with the cross-relaxation time in the rotating frame between the rare and the abundant spins. In this manner, even though the S resonance

Figure 56 The 24 MHz ^{13}C NMR spectra of polycrystalline adamantane. (a) FT of a FID after a 90° pulse; (b) Cross polarization without decoupling; (c) Cross polarization and decoupling.³⁵¹ (Reproduced by permission of the American Institute of Physics)

may be hard to observe directly, it could be seen indirectly by its effect on the I spins.

A simplification of the experimental technique and the theoretical analysis was subsequently made by Lurie and Slichter³⁴⁷ in 1963 and published in 1964. In this method, the I spin system is spin-locked at exact resonance while the rare spin is simultaneously irradiated with a train of coherent pulses close to its Larmor frequency. Thermal mixing of the two spin systems occurs via cross relaxation when both these rf fields are on. The combined system approaches thermodynamic equilibrium, characterized by a common spin temperature. The S channel rf field is then turned off for a period greater than $(T_2)_S$. This method differs from the Hartmann and Hahn technique in the manner in which M_I is brought parallel to $(H_1)_I$ and the methodology for inducing changes in the S magnetization. A variation of the Lurie–Slichter method was later developed by Mansfield and Grannell³⁴⁸ in 1971 for the improved resolution of small resonance shifts of dilute nuclear spin systems. Bleich and Redfield,³⁴⁹ around the same time, combined the Hartmann–Hahn method with solid state spin decoupling in order to improve resolution of rare spins in solids, and later proposed still another type of Hartmann–Hahn double resonance technique in solids which is particularly suited for the high-resolution spectroscopy of spins with low magnetogyric ratios.³⁵⁰

Direct Observation of Dilute Spins by Cross Polarization

The indirect double resonance methods in solids for rare spins are not useful for the study of high-resolution spectra

Figure 57 Cross polarization FID and spectrum of ^{13}C in durene, showing lines from the six aromatic and four methyl carbons.³⁵³ (Reproduced by permission of the American Institute of Physics)

because the spectra observed are, in effect, broadened by the very coupling which makes them possible. Alex Pines, then a graduate student with John Waugh, conceived the idea of dividing the experiment into two parts: first, the rare spins are polarized by the Hartmann–Hahn procedure ('cross polarization'), and second, the rf irradiating the rare spins is turned off and the FID corresponding to the rare spin developing under chemical shifts and decoupled from all the abundant spins is recorded. Pines described this technique at the 1972 ENC, showing beautiful slides of the enhancement of the sensitivity and resolution by the CP experiments with abundant spin (proton) decoupling, and a paper entitled 'Proton Enhanced Nuclear Induction Spectroscopy' soon appeared in the *Journal of Chemical Physics*.³⁵¹ The initial ^{13}C spectra of polycrystalline adamantane obtained in natural abundance of ^{13}C , with and without cross polarization, and with and without proton decoupling, are shown in Figure 56. Using this technique, Pines et al. determined the ^{13}C chemical shielding parameters for a number of organic compounds.³⁵² The utility of such experiments was clear, and its use rapidly became widespread.

The applications of cross polarization are numerous. An early study of the chemical shielding tensors of all the carbons in the single crystals of durene by Pausak, Pines, and Waugh³⁵³ is illustrated in Figure 57, where the expected 10 lines were resolved. The measurement of chemical shielding tensors has provided a versatile tool for the study of the structure and dynamics of molecules. An interesting application of the chemical shielding anisotropy to probe solid state structure was initially proposed by Rimpmeester et al.,³⁵⁴ who examined the ^{129}Xe spectra of the gas intercalated into several solids. The spherically symmetric isolated molecule shows no chemical shielding anisotropy. Any observed anisotropy must consequently arise from the asymmetry in the immediate environment of the atom.

Wind et al.³⁵⁵ proposed a novel solid state NMR experiment that uses dynamic nuclear polarization for further enhancement of the ^{13}C signals. The experiment was the result of the NMR investigations of coals, which inherently contain free electrons, typically 10^{19} per gram. It was observed that both the proton and ^{13}C signals could be enhanced by significant amounts (one order of magnitude for protons and two orders of magnitude for ^{13}C , the latter also containing a contribution from proton–carbon cross polarization) by irradiating near the electron Larmor frequency. Magic angle spinning can also be performed.³⁵⁶ Such an experiment provides high spatial selectivity and may serve as an important tool to reduce the measuring time for the ^{13}C spectra for nuclear spins that are near electron spins.

The possibilities of combining various techniques in solid-state NMR appear to be endless! Selective pulse experiments have found applications in the simplification of spectra and in the study of slow dynamic processes such as chemical exchange and spin diffusion. Selective excitation can be achieved either by application of weak rf pulses of appropriate frequency or by a DANTE sequence, which consists of a series of short, intense rf pulses. By adjusting the time between the pulses, one of the pulse sidebands may be centered on the transition corresponding to the selected resonance. The DANTE pulse sequence is appropriate in MAS experiments where the sidebands are separated by the spinning frequency.

Magic Angle Spinning Returns

The initial attempts to narrow lines in solids by magic angle spinning were of limited success as we have seen, because the dominant dipolar interactions are, in many systems, too large to be eliminated with achievable spinning speeds. The principal methods developed, however, to overcome these interactions—multiple pulse techniques for homonuclear interactions and cross polarization/high-power decoupling for many heteronuclear systems—have their own limitations. These methods specifically eliminate dipolar interactions but, by their nature, do not affect chemical shift anisotropy. It may be an advantage to retain the chemical shift anisotropy information in some experiments, but chemical shift anisotropy can be greater than the total chemical shift range (e.g. of protons) and in that case it severely limits the practical applications for routine analytical purposes. The potential of combining MAS with multiple pulse or CP methods thus became attractive in order to achieve maximum resolution.

Waugh considered combining MAS with the Pines–Gibby–Waugh CP technique, but did not pursue the idea aggressively since he was concerned that the spinning might behave like random molecular motions in removing the very static dipolar coupling required for cross polarization. Schaefer and Stejskal, who had revived MAS for ^{13}C NMR, quickly took up the new CP techniques as well, but in completely different experiments. They did not try the combined techniques for a year or so, largely because of limitations in their apparatus and concern about wearing out rotors while trying to establish optimum conditions for the new experiment. Nevertheless, the first CP MAS experiment was performed by Schaefer and Stejskal³⁵⁷ in 1975, the ^{13}C spectrum of poly(methyl methacrylate) as reproduced in Figure 58. A comparison with the ‘static’ sample spectrum shows the remarkable difference in the two

Figure 58 Combined cross polarization and magic angle spinning applied to the ^{13}C spectrum of poly(methyl methacrylate).³⁵⁷ (Reproduced by permission of the American Chemical Society)

spectra and a strong low field signal due to nonprotonated carbonyl carbon of poly(methyl methacrylate) can be clearly seen. After collecting data on a variety of solids, Schaefer and Stejskal submitted a brief communication to the *Journal of the American Chemical Society*, only to have it rejected initially because of the negative comments of the referees who wrote ‘basically there should not be polarization transfer due to a dipolar interaction between nuclei in a sample being spun rapidly at the magic angle.’ The skepticism was well founded on theoretical grounds, but the experiments were genuine. With some alterations to the manuscript, the paper was eventually accepted. Actually, as became apparent in later studies, the cross polarization dynamics in CP MAS NMR are not as simple as in plain CP NMR. Schaefer’s historical sketch (*Schaefer, Jacob: A Brief History of the Combination of Cross Polarization and Magic Angle Spinning*) describes the unusual effects observed and their explanation in a paper by Stejskal, Schaefer, and Waugh³⁵⁸ in 1977.

The appearance of liquid-like spectra in solid polymers eventually obtained using CP MAS experiments made this technique a standard tool in polymer research. CP MAS has been extensively employed for the chemical characterization of coal and related materials for differentiating the aromatic and aliphatic contents, but it has not been possible to resolve the aromatics and condensed aromatics in the CP MAS spectra of coals. The shielding anisotropies of such carbons are significantly different, giving better resolved spectra without MAS.³⁵⁹

In a normal CP MAS experiment, the coherent dipolar decoupling also eliminates the scalar ^1H – ^{13}C coupling in the ^{13}C spectrum. In order to make CP MAS experiments more valuable in structural chemistry, advances have been made by Terao et al.^{360–362} and by Zilm and Grant³⁶³ that retain the indirect spin–spin couplings in the high-resolution CP MAS experiments. Also, Opella and Frey³⁶⁴ developed a technique to assist in the assignment of lines by making use of the large difference in dipolar broadenings of the resonances of carbons with protons attached compared with those without protons.

The possibility of combining multiple pulse experiments such as WAHUA with MAS was first discussed by Haeberlen and Waugh in 1968, but was not implemented for many years because of both theoretical concerns and practical problems in dealing with two sensitive technologies. The initial combined magic angle multipulse experiments in which both homonuclear dipolar interactions and chemical shift anisotropies were sufficiently removed to resolve chemically shifted fluorines in a randomly oriented solid were described by Gerstein et al.³⁶⁵ and by Schnabel et al.³⁶⁶ The sample chosen by Gerstein to illustrate the effect was Kel-F (polymerized $\text{FCIC}=\text{CF}_2$). The rotation speed was 2.5 kHz and the MREV-8 pulse sequence was used, resulting in a chemical shift scaled by roughly $\frac{1}{3}\sqrt{2}$. The spectrum is shown in Figure 59. The figure shows the spectra obtained with MREV-8, as well as the combined magic angle spinning and multipulse techniques. The natural linewidth of the ^{19}F resonance for a single free induction decay was 10 kHz. The residual linewidth in the combined rotation and multipulse sequence was attributed to the differing stereochemical environments of the fluorine nuclei. The two peaks separated by 23 ppm were identified as fluorines bound to the same carbon and a carbon bound to a chlorine. The method was called CramPS for *C*ombined *R*otational And *M*ultiple *P*ulse Spectroscopy. Subsequently, other pulse sequences such as the 24-cycle sequence BR-24 were employed to improve the efficiency.

Line-Narrowing Techniques for Quadrupolar Nuclei

Line-narrowing techniques for the solid state NMR spectra of quadrupolar nuclei have also been developed. Alex Pines and his group at Berkeley have been particularly prominent in this area. They were able to eliminate the first-order quadrupolar broadening in deuterium by using magic angle spinning along with sampling that was synchronous with rotation frequency.³⁶⁷ The linewidth could be reduced by three orders of magnitude by the simple MAS experiment, but the stability and the setting of the magic angle was very critical. Further improvements in spinner design permitted the application of MAS to deuterium in solids where the powder static linewidth can be over 255 kHz.

For deuterium, with $I = 1$, Pines utilized the fact that the $1 \leftrightarrow -1$ transition is independent of sample orientation and hence leads to sharp lines. We discuss multiple quantum transitions in Section 11, but it is appropriate to point out here that the Pines group combined double-quantum spectroscopy with magic angle spinning.³⁶⁸

Eric Oldfield and his co-workers explored the problem of line narrowing for nonintegral spin quadrupolar nuclei, where the second-order quadrupole interaction dominates the breadth of the $(\frac{1}{2}, -\frac{1}{2})$ spin transitions. At high magnetic field this

Figure 59 The ^{19}F spectrum of Kel-F obtained with a MREV-8 sequence (top) and MREV-8 combined with magic angle spinning (bottom).³⁶⁵ (Reproduced by permission of the American Institute of Physics)

effect is reduced to the point that many nuclei are amenable to study. For systems with large quadrupole coupling constants (of the order of a few MHz), they observed the optimum line narrowing by rapid sample rotation at angles other than $54^\circ 44'$. For ^{23}Na in Na_2MoO_4 , an order of magnitude reduction in breadth of the central transition was achieved by rapid rotation at 36° or 75° , over twice that achieved at $54^\circ 44'$.³⁶⁹ The effect originates from the more complex angle dependence of dipolar and chemical shift interactions.

Pines made the most general approach to the problem of averaging second-order quadrupolar interactions. In his historical sketch (*Pines, Alexander: Solid State NMR: Some Personal Recollections*), he says:

The solution, for which we developed both the theory, with independent work by Llor and Virlet, and demonstrated the initial experiments (with the indispensable support of Berkeley's machine shop), involved motional averaging through sample spinning about two axes. Two techniques emerged—dynamic angle spinning (DAS) and double rotation (DOR)—which brought to quadrupolar nuclei the kind of resolution previously reserved for spins $\frac{1}{2}$. During this period our laboratory often felt

like a dental clinic, with the whizzing and whining sounds and rich harmonics of dynamic-angle and double rotor probes.

With the development of the techniques described in this Section, along with many others that we have not been able to include, the NMR spectroscopist was largely freed of the constraints imposed by line broadening in solids. Information of value in chemistry, materials science, and biology could now be extracted from solids, as well as liquids.

MULTINUCLEAR MAGNETIC RESONANCE

Although NMR studies of several nuclei have been discussed in previous sections, much of the early history was dominated by ^1H NMR. Even now, proton NMR is studied far more than that for any other single nucleus because of its sensitivity, virtually 100% isotopic abundance, and presence in almost all molecules of interest. NMR imaging (which accounts for a significant fraction of all current NMR measurements) is devoted almost exclusively to ^1H NMR since this technique focuses primarily on water in the human body. The dominance of ^1H NMR has given rise to the practice of referring to non- ^1H nuclides as ‘other nuclei’ and to their study as ‘heteronuclear NMR’, a term that may lack grammatical precision but is correctly understood by all NMR spectroscopists.

Some NMR spectroscopists directed their attention toward a particular nucleus, while others wanted to explore a wide range of nuclei. Otto Lutz’s historical sketch (*Lutz, Otto: Heteronuclear Magnetic Resonance*) mentions his observation of more than 50 isotopes, beginning in 1975 with a Bruker high-power pulse spectrometer that was also capable of carrying out high-resolution studies with an internal deuterium lock, along with a number of homemade probes. (The instrument was called MONALISA—a name that contains the symbols for 11 different NMR-active isotopes when read both forward and backward.)

In general, the early NMR spectrometers were not designed to facilitate multinuclear observations, as pointed out by Paul Ellis in his historical sketch (*Ellis, Paul D.: Multinuclear MR Experiments, the Surrogate Probe Strategy, and Other Fun & Games*):

In the 1960s and early 1970s, it was common for manufacturers of NMR spectrometers to build the spectrometer around specific nuclei rather than being broadbanded. Hence, if you purchased your spectrometer with ^1H , ^{13}C , and ^{31}P observe capabilities, you would get three transmitters, three local oscillators, three preamps, and, depending upon the manufacturer, three probes. It was a great marketing tool designed to bring in a gazillion dollars per spectrometer but a poor way to do science. This picture started to change when Dan Traficante learned how to ‘fake’ a spectrometer into thinking it was performing a ^{13}C experiment when it was really looking at ^{29}Si .

This work led to Varian’s ‘Gyrocode Observe’ option, the first commercially available multinuclear observe accessory, which soon gave way to true frequency synthesizers. Over the last 20 years there has been an increasing awareness of the rich information available in the study of many different nuclei. With FT methods, highly developed double resonance techniques, and spectrometers based on frequency synthesizers with broadband probes, the NMR spectroscopist in the mid-1970s was equipped to make progress with almost any isotope

chosen for study in liquids. Moreover, rapid development of multiple pulse methods and magic angle spinning also opened the door to the study of many nuclei in solids.

We have already described many of the early studies of ^{19}F and ^{31}P NMR. These nuclides of spin $\frac{1}{2}$ usually display sharp lines and have much larger chemical shift ranges than ^1H , so investigations with magnets of limited homogeneity could often be carried out more readily with these nuclei. We have also told the story of the emergence of ^{13}C studies, as double resonance and Fourier transform methods developed, and have pointed out applications of deuterium NMR. The Periodic Table is large, however, and almost every element has at least one isotope (often several) with nuclear spin, as indicated in Figure 60. In fact, all elements except Tc, Pm, Ar, and Ce in the Periodic Table up to and including lead have one or more suitable stable isotopes accessible to NMR. In 1977, when Harris and Mann completed their comprehensive survey of multinuclear magnetic resonance,³⁷⁰ only one spin- $\frac{1}{2}$ nucleus (^{103}Rh) and 10 quadrupolar nuclides had not been observed directly. Since then, as mentioned later, at least limited studies have been carried out with four of these nuclei, leaving only ^{91}Zr , ^{105}Pd , ^{177}Hf , ^{179}Hf , ^{191}Ir , ^{193}Ir , and ^{197}Au unobserved directly, but in some instances studied by double resonance methods.

In some ways each isotope is unique, and a historical account perhaps should treat each one separately. We present here a short description of the early NMR history and of some later developments for those nuclides that have engendered the most interest or have demonstrated some particularly important principles. For completeness, the section concludes with a brief summary of early work with several rather infrequently studied nuclides.

General Features of ‘Heteronuclear’ Magnetic Resonance

The discovery of nuclear induction resulted from Felix Bloch’s desire to make more accurate measurements of the magnetic moments of nuclides, and much of the early work in multinuclear MR dates back to the late 1940s when many magnetic moments were determined by Bloch, Proctor, and Yu. In this section, we emphasize the historical developments related to chemical applications and in most instances do not report the initial measurements of magnetic moments.

The problems associated with heteronuclear NMR generally arise from (i) low signal-to-noise ratios due to small magnetic moment and/or low natural abundance, (ii) large linewidths for quadrupolar nuclides, or (iii) long relaxation times. The solubility of compounds in appropriate solvents also presented initial difficulties in many compounds for high-resolution studies. However, the favorable factor, which was well recognized, is the large chemical shift range for many nuclides, which demanded much less effort to resolve spectral lines.

Low natural abundance could sometimes be compensated by artificial isotopic enrichment of the samples, and in some instances (notably ^{13}C) could be advantageous since homonuclear coupling constants are usually not observed, resulting in spectral simplification.

Although quadrupolar nuclides have always been at a disadvantage as compared with those of spin $\frac{1}{2}$, it was found that the problems were often less severe than might be anticipated. Some nuclei (e.g., ^2H , ^6Li , ^{11}B , and ^{51}V) have

Figure 60 Periodic Table of the Elements, showing nuclides that have been observed directly by NMR. Adapted from Harris and Mann.³⁷⁰ (Courtesy of R.K. Harris)

relatively small quadrupole moments, and others with large moments can often provide useful information in chemical species in which the electric field gradient is small (e.g., ions).

The development of ‘shiftless’ relaxation agents, such as chromium acetylacetonate $[\text{Cr}(\text{acac})_3]$, which shorten relaxation times without significantly altering chemical shifts, provided a valuable means to shorten the relaxation time of such nuclei as ^{15}N , ^{29}Si , and ^{57}Fe , and hence to facilitate their study.

Nitrogen-14 and Nitrogen-15

As pointed out in Section 2, ^{14}N was the nucleus which led to one of the first discoveries of the chemical shift by Proctor and Yu⁴⁴ in 1950. During the next few years, chemical shifts in a large number of compounds were determined by Masuda and Kanda³⁷¹ and Holder and Klein.³⁷² They established general correlations with molecular structure and found that nitrogen shifts in nitrates, nitrites, and ammonium ions were concentration- and pH-dependent. In 1957, Ogg and Ray³⁷³ reported that the ^{14}N spectrum of ammonia consisted of a broad signal as compared with that in the NH_4^+ ion, and thus demonstrated the role of charge asymmetry about this quadrupolar nucleus in determining relaxation times.

A range of about 1000 ppm has been observed for ^{14}N chemical shifts, but for a given class of compounds the range is often only 10–50 ppm. Nevertheless, for molecules with relatively narrow lines, useful structural information can be obtained as pointed out by Michal Witkowski in his historical sketch (*Witkowski, Michal: A Short Story about Nitrogen NMR*). Because of the sensitivity of ^{14}N chemical shifts to structural changes, ^{14}N NMR has been extensively employed in organic and inorganic compounds, as well as in metal complexes. ^{14}N NMR parameters are diagnostic of coordination, chelation,

protonation, conformation, stereochemistry, and solution equilibria and other dynamic processes such as ligand exchange, intramolecular motions, and tautomerism. The book edited by Webb and Witkowski,³⁷⁴ as well as review articles,³⁷⁵ attest to the popularity and value of such studies.

Although ^{14}N lines are often sufficiently narrow for the determination of chemical shifts, there is usually little information on scalar couplings, especially through more than one bond. Moreover, many compounds have lines that are too broad even for the determination of chemical shifts. The ^{15}N nucleus is an ideal complement to ^{14}N , but its low natural abundance (0.365%) and small magnetic moment, together with a long T_1 , combined to deter study of this isotope. The first direct observation of ^{15}N NMR at natural abundance occurred as late as 1964 by Ray,³⁷⁶ but for many years the only useful studies in chemistry were made with enriched materials. Even observing highly enriched ^{15}N NMR was a real feat at 6 MHz with the spectrometers of the period, so indirect detection via INDOR or other double resonance methods often found favor, especially for studying ^{15}N compounds at low concentration as in investigations of hydrogen bonding,³⁷⁷ since ^1H sensitivity is 1000 times that of ^{15}N .

Direct observations were carried out, however. Joe Lambert’s historical sketch (*Lambert, Joseph B.: The First Observation of Nitrogen-15 Nuclear Magnetic Resonances*) describes his work in J. D. Roberts’s laboratory at Caltech in finding a resonance in 96% enriched nitric acid during the summer of 1963. By sequential synthesis of several labeled molecules, Lambert, Binsch, and Roberts were able to stretch their ^{15}N supply and report the spectra of a number of organic molecules.³⁷⁸ Further efforts yielded data on one-bond ^{15}N –H coupling constants and their correlation with molecular structure, the first measurement of a ^{15}N – ^{15}N coupling constant,³⁷⁹ and a great deal of other information on the use of ^{15}N in

organic chemistry. Many other studies in a number of laboratories followed, and as FT and double resonance methods were introduced, the more routine study of ^{15}N , even at natural abundance, became feasible. The negative NOE arising from the negative magnetogyric ratio of ^{15}N was not expected by early workers and caused considerable confusion, resulting in the necessity of studying relaxation processes in detail. 'Shift-less' relaxation reagents have been employed to facilitate the observation of ^{15}N NMR. The ^{15}N chemical shifts of up to 1400 compounds and spin-spin couplings (^{15}N -X) for about 1200 structures were reported in 1981 by Martin, Martin, and Gouesnard.³⁸⁰ During the 1990's, as we shall see in Section 14, many investigations of biopolymers have made use of ^{15}N chemical shifts, but with a return to indirect, rather than direct, detection via two- and three-dimensional NMR methods.

High-resolution ^{15}N NMR spectra in the solid state have become useful in studying biologically important nitrogen linkages, including hydrogen bonding. The full range of NMR methods is increasingly being employed in the study of natural products, usually with biosynthetic ^{15}N enrichment. Stejskal and Schaefer have used double cross polarization, the transfer of proton magnetization to either ^{15}N or ^{13}C , then from one to the other, to study protein turnover in soybean leaves grown with $^{15}\text{NH}_4^{15}\text{NO}_3$ and $^{13}\text{CO}_2$ ³⁸¹ and they have used CP MAS to investigate nitrate metabolism.³⁸² Cross, DiVerdi, and Opella³⁸³ have outlined strategies for biopolymers and applied them to bacterial and viral DNA to show hydrogen bonding and neighbor effects within and between strands. Dilute ^{15}N spin exchange (NOESY) techniques were used by Cross, Frey, and Opella in 1983 to locate ^{15}N sites in α -helical bacteriophage coat proteins.³⁸⁴ Several applications of ^{15}N NMR in inorganic chemistry have also been made using high-resolution solid state NMR techniques, including studies of nitrogen complexes and adsorption. CP MAS ^{15}N spectra for pyridine and ammonia on γ -alumina and mordenites have been investigated by Ripmeester,³⁸⁵ Maciel,³⁸⁶ Ellis³⁸⁷ and their co-workers.

Silicon-29

Lauterbur and his co-workers³⁸⁸ observed ^{29}Si resonances at the natural abundance of 4.7% as early as 1956, and in 1962 Baker²⁴⁷ used INDOR to improve the signal-to-noise ratio in the ^{29}Si spectrum of a 20 mol % solution of tetramethylsilane (Figure 61). However, the generally low receptivity (about twice that of ^{13}C) precluded any significant studies until modern instrumentation became available. Even then, the negative magnetogyric ratio and relatively long T_1 presented experimental problems. The early studies established the overall chemical shift range, demonstrated some ^{29}Si - ^{19}F coupling constants of 200–300 Hz, and showed significant line broadening for silicon directly bonded to quadrupolar nuclei such as nitrogen and the halogens.

In the 1970s ^{29}Si studies underwent a renaissance, as a number of groups applied FT techniques in studying a variety of substances. For example, Robin Harris and co-workers found that the wide chemical shift range for ^{29}Si made it invaluable for examining silicones³⁸⁹ and silicates, but the absence of homonuclear spin coupling at natural abundance of 5% limited interpretation. They decided to use enriched samples and obtained the first such spectra. As Harris says in

Figure 61 INDOR spectrum of ^{29}Si in tetramethylsilane observed by 60 MHz ^1H NMR.²⁴⁷ (Reproduced by permission of the American Institute of Physics)

his historical sketch (*Harris, Robin K.: Chemical Magnetic Resonance goes Multinuclear*):

At one point, I believe we purchased the total supply (at least in the UK) of ^{29}Si -enriched silica—which is one way to stymie any competition! Soon we progressed to the first very high field ^{29}Si spectra (Bruker WM-500 ...). With the ^{29}Si enrichment, coupling became important and, in his Ph.D. with me, Chris Knight used both first-order and second-order spectra to yield the first unequivocal structural determination of many species present in the (potassium silicate) solutions.

Günter Engelhardt's historical sketch (*Engelhardt, Günter: Silicon-29 NMR of Silicates: From Liquids to Solids. An Historical Perspective*) describes other approaches in his laboratory and elsewhere to the study of silicates in solution and the progression to the study of solids as CP MAS methods were developed. Engelhardt collaborated closely in this work with Endel Lippmaa and his colleagues in Tallinn, Estonia where they had developed excellent methods for the study of solid ^{13}C , concurrently with the more widely known work in western countries. In spite of initial difficulties in applying the techniques to ^{29}Si , by 1977 they had successfully measured the first highly resolved ^{29}Si CP MAS spectra of solid silicates and organosilicon compounds.³⁹⁰ Excited by these results, Jacek Klinowski began a long series of fruitful studies of ^{29}Si (and later ^{27}Al) in zeolites. In *Klinowski, Jacek: Historical Sketch: Molecular Sieves*, Klinowski points out:

MAS NMR opened a completely new layer of insight into the structure of molecular sieves, and for several months one could simply take a sample off the shelf to obtain results which were novel, fascinating and important.

Tritium

As we saw in Section 2, tritium was of considerable interest to Felix Bloch in his early efforts to pin down precise values of the magnetic moments of the three isotopes of hydrogen and of the neutron. The magnetic moment of tritium was determined in 1947, independently by Anderson and Novick³⁹¹ and Bloch et al.^{26,392}

The first high-resolution NMR study of tritium was reported by George Tiers and co-workers³⁹³ in 1964. They studied neat ethylbenzene containing 1 atom % tritium. The experiments were performed on an HR-40 spectrometer. The spectrum consisted of two first-order multiplets corresponding to CH_2T and CHT , from which values of the two- and three-bond ^3H - ^1H couplings and the tritium chemical shifts could be

easily determined. In 1971, Elvidge et al.³⁹⁴ began continuing development of ^3H NMR and reported the spectra of several compounds. ^3H NMR has been used for the assignment of complex proton spectra, obtained before the advent of high magnetic fields, in such compounds as phenanthridine, pyrrole, benzamides, toluene, and fatty acids. Tritium NMR has also been employed in a number of biomolecular and reaction mechanism studies, and Newmark et al. used ^3H NMR to study the pentose pathway in erythrocytes, a living cellular system.³⁹⁵

By the standards of radioactive tracers, a very large amount of tritium is required for NMR study, but the weak β -radiation is blocked by the wall of the NMR sample tube. Nevertheless, suitable precautions are required to avoid the fracture of sample tubes or the excessive build-up of pressure from formation of tritium gas from radiolysis. A special Biotechnology Resource for studying tritium NMR under conditions that minimize potential hazards was established by the National Institutes of Health at the State University of New York in Stony Brook in the early 1980s and relocated to the University of California in Berkeley about 1985.

Oxygen-17

Natural abundance ^{17}O was first observed by Alder and Yu³⁹⁶ as early as 1951, but it took several years until Weaver, Tolbert, and La Force studied a variety of compounds to investigate ^{17}O chemical shifts.³⁹⁷ With slow passage and dispersion mode, a signal-to-noise ratio of 50 was obtained for H_2O (natural abundance). A chemical shift range of about 700 ppm was observed, with water appearing at the highest field. A few years later, Dharmatti et al.,³⁹⁸ Christ and co-workers,^{399,400} and Figgis et al.⁴⁰¹ showed that useful information on organic and inorganic molecules could be derived from ^{17}O NMR data obtained on wide-line spectrometers with large-bore sample tubes.

With more modern instrumentation, a number of workers have shown that the chemical shift range is over 1200 ppm and have established several correlations of the ^{17}O chemical shifts with structural parameters in molecules. Important among these are correlations with mean excitation energy, π -bond order, and the chemical shifts of nuclei such as carbon and nitrogen. A correlation of the ^{17}O chemical shift with the number of metal atoms coordinated to it has been observed.

^{17}O NMR linewidths have been observed to range from 0.5 Hz to 9000 Hz, with typical values on the order of 100 Hz. Thus it has been possible to measure many spin-spin coupling constants, even with other quadrupolar nuclei. The one-bond H- ^{17}O coupling constant is typically 100 Hz and has been measured as 106 Hz in H_3O^+ .^{402,403}

Many investigators have taken advantage of the significant chemical shift range and linewidth variation to use ^{17}O NMR for structural studies, including estimates of bond polarization, hydrogen bonding, kinetics of oxygen exchange, water orientation in lyotropic phases, and ionic solvation. ^{17}O NMR has also been employed to investigate the structure of biologically relevant medium-sized molecules such as amino acids, small peptides, monosaccharides, polyphosphates, and nucleosides. Eric Oldfield's historical sketch (*Oldfield, Eric: NMR Adventures in Chemistry and Biology*) summarizes his ^{17}O magic angle spinning studies in a variety of

Figure 62 ^{11}B NMR spectra at 12.8 MHz of two pentaboranes.⁴⁰⁷ (Reproduced by permission of the American Institute of Physics)

solids, including zeolites, heme proteins, and high-temperature superconductors.

Boron-10 and Boron-11

Boron, with two NMR active isotopes, was among the first elements to attract the attention of NMR spectroscopists in the 1950s. Both nuclides have weak quadrupole moments, but ^{11}B is more often studied due to its better sensitivity and greater natural abundance, even though the spectral lines are usually sharper for ^{10}B than for ^{11}B .

The first ^{11}B spectra, obtained by Ogg⁴⁰⁴ in 1954, were of NaBH_4 (in aqueous solution) and liquid diborane. The spectrum of sodium borohydride showed a five-line pattern with the intensity ratio of 1 : 4 : 6 : 4 : 1 with a ^{11}B - ^1H coupling of 82 Hz, which established the equivalence of the four protons, while for diborane the spectrum confirmed the bridge structure. At that time the structures of a number of boranes were in question, and the type of bonding in boranes (with nonclassical bridging hydrogens) was a topic of intense interest to both theoreticians and experimentalists. During the next few years, Shoolery et al.,^{405,406} Williams et al.,⁴⁰⁷ and others established the structures of several boranes using ^{11}B , as well as ^1H NMR. For example, Figure 62 shows the ^{11}B spectra at 12.8 MHz of two different pentaboranes, stable B_5H_9 and unstable B_5H_{11} . The success of NMR in elucidating the structures of the boranes provided an early demonstration of the value of the new method in chemistry and helped establish its credibility even before the wave of organic structure elucidations that would soon follow.

Subsequent investigations by a number of research groups have established a chemical shift range for boron of about

220 ppm, with distinctly different ranges for trigonal and tetrahedral boron. Well over 3000 trigonal and tetrahedral boron compounds have now been examined by ^{11}B NMR. One-bond ^{11}B -X coupling constants ranging from 1–5 Hz in BF_4^- up to more than 1 kHz for $\text{X} = ^{119}\text{Sn}$ or ^{207}Pb have been observed. ^{11}B NMR has been a valuable tool in elucidating the structure and bonding in polyhedral boranes and carboranes.

The Noble Gases

Because of their simplicity and symmetry, the noble gases have found particular use in the development and testing of various theories, and as probes of environmental perturbations. ^3He and ^{129}Xe are spin- $\frac{1}{2}$ nuclei, while ^{131}Xe has a quadrupole moment as do ^{21}Ne and ^{83}Kr . Argon has no magnetically active stable isotope.

In Section 4, we mentioned the work by Streever and Carr¹⁶³ in measuring T_1 in ^{129}Xe as a function of temperature in the liquid state and as a function of pressure in the gaseous state, and in discovering a strong density-dependent shift in the resonance frequency. Torrey⁴⁰⁸ pointed out a connection, given by Ramsey's theory of chemical shifts, between the chemical shift and the spin-rotational coupling constant in ^{129}Xe , a generalization that has been used subsequently in the analysis of other relaxation data. The sensitivity of the chemical shift has been exploited by using ^{129}Xe as a probe of microporous solids. For example, J. Fraissard's historical sketch (*Fraissard, J.: A Look at Solid Catalysts by NMR*) describes the analysis of chemical shift variations to determine the dimensions and form of the internal free volumes of zeolites, to examine structural defects and short-range crystallinity, and to obtain a great deal of useful information on dynamic processes. In Section 15, we shall describe further examples in the study of materials.

In 1963, shortly after the discovery of covalent xenon compounds,⁴⁰⁹ Brown, Whipple, and Verdier⁴¹⁰ reported an indirect NMR study of XeOF_5 , XeF_4 , and XeF_2 through ^{19}F observation. The first direct measurement of the ^{129}Xe chemical shift in such compounds was made by Seppelt and Rupp^{411,412} in 1974, and new chemical shift data for a wide range of oxidation states of Xe were subsequently obtained by Schrobilgen et al.⁴¹³ Chemical shifts range over 7500 ppm and coupling constants, particularly with ^{19}F , have been observed from 100 Hz up to more than 7500 Hz. The parameters are very sensitive to solvent, temperature, and concentration. This has been attributed to the oxidation state of Xe, the ionic character of the Xe-X bond, and solvent interactions.

Helium has played an important role in the development of various theories and concepts in physics because of its unique properties, and ^3He has likewise found favor for certain physical studies. ^3He has a sensitivity which is 40 % of that of ^1H but a natural abundance of only 0.01 %. Much of the work involves the solid and superfluid states. In 1956, Walters and Fairbank^{414,415} used ^3He NMR to study the phase diagram for ^3He - ^4He solutions at 0.8 K and to examine the pressure-dependence of the density and magnetic susceptibility of ^3He below 1 K. Later, Bernier and co-workers^{416,417} developed pulse methods to measure the nuclear magnetic susceptibility in solid ^3He . More recently, Friedman, Millet, and Richardson⁴¹⁸ discovered that liquid ^3He at 10 mK provided efficient relaxation of ^{19}F spins on the surface of

Teflon microspheres, and Waugh and co-workers⁴¹⁹ used this phenomenon to explore spin diffusion in single-crystal CaF_2 at very low temperatures.

Recent work by Diehl and co-workers⁴²⁰ has focused on environmental perturbations in the chemical shift of ^3He , dissolved in solids such as Pyrex or Suprasil glasses and in liquid crystals, while Saunders, Anet, and co-workers⁴²¹ used ^3He to probe the interior of fullerenes. The chemical shift of ^3He was interpreted in terms of ring currents in C_{60} and C_{70} .

NMR work on ^{21}Ne and ^{83}Kr has largely been confined to physics problems related to nonspecific intermolecular interactions. Relaxation times and medium shifts have been used to study intermolecular interactions between these atoms from the dilute gas all the way to the pure liquid and solid phases.

Iron-57, Cobalt-59, and Nickel-61

These three elements, which have many chemical similarities, are very different in their NMR properties. The only naturally occurring isotope of cobalt is ^{59}Co . It is less sensitive than protons only by a factor of about three, thus putting it among the top six nuclear species in terms of ease of detection. However, it has a spin of $\frac{7}{2}$ and a large quadrupole moment, and its range of chemical shifts of about 18 000 ppm is among the largest known. Most NMR data come from hexacoordinated Co(III) , which is diamagnetic.

The ^{59}Co nucleus occupies a unique position in the history of NMR. In 1951, Proctor and Yu⁴²² discovered that the resonance frequency of ^{59}Co may vary by as much as 1%, depending upon the compound investigated. Hence, in spite of broad lines (several kHz for asymmetric coordination), it was feasible to acquire a significant amount of chemical shift data for ^{59}Co during the early days of NMR.

The first systematic ^{59}Co chemical shift studies were reported in 1957 by Rex Richards and co-workers,⁴²³ who rationalized the chemical shifts in terms of the paramagnetic term in Ramsey's shielding equation, an important early test of this theory. Cobalt shieldings were found to be relatively insensitive to concentration but to vary up to about 200 ppm in different organic solvents. The shieldings in the solid and solution were found to be the same within the experimental error of about 200 ppm. The ^{59}Co shieldings exhibit a linear dependence on temperature of about 1–3 ppm per degree, a feature that was later exploited by George Levy and co-workers in their estimation of the temperature of NMR samples.⁴²⁴

Increasing pressure has been found to cause an increase in cobalt shielding,⁴²⁵ while shieldings have also been used as a sensitive measure of stereochemistry. Gasser and Richards⁴²⁶ studied the rate of exchange between ethylenediamine and hexammine cobalt(III) ion in the late 1950s. Subsequently, ^{59}Co NMR has also been employed to study the binding of anions and cations in the second coordination sphere of cobalt(III) complexes. Martin and Fung⁴²⁷ and Craighead, Jones, and Bryant⁴²⁸ have examined the rather strong binding of phosphate to cations such as Co(en)_3^{3+} .

Although an extensive literature dealing with cobalt chemical shifts in a variety of Co(III) complexes is available, very few instances of spin-spin couplings involving ^{59}Co have been observed, partially because many ^{59}Co lines are

very broad. Linewidths span the range from 175 Hz for $[\text{Co}(\text{CN})_6]^{3-}$ to 40 kHz for $\text{HgCo}_2(\text{CO})_8$. In $[\text{Co}(\text{CN})_6]^{3-}$, a ^{59}Co – ^{13}C coupling constant of 126 Hz was obtained by Traficante and Simms⁴²⁹ from the satellite peaks in the ^{59}Co spectrum, while a value of 287 Hz for the ^{59}Co – ^{13}C coupling constant in $\text{Na}[\text{Co}(\text{CO})_4]$ was obtained by Lucken et al.⁴³⁰ Possible relaxation mechanisms contributing to ^{59}Co NMR linewidths have been considered by Yamasaki et al.⁴³¹ and Ader and Loewenstein.⁴³²

In contrast to ^{59}Co , ^{57}Fe (the only NMR-active isotope of iron) has a natural abundance of only 2% and a very small magnetic moment, leading to very low receptivity. With a spin of $\frac{1}{2}$, it has been found to have generally long relaxation times in diamagnetic compounds. These factors combined to prevent any significant application of ^{57}Fe NMR until the advent of more sensitive and versatile instruments.

The first ^{57}Fe NMR signal in a diamagnetic compound, $\text{Fe}(\text{CO})_5$, was obtained by Schwenk⁴³³ in 1970 using the pulse technique of Kaufmann and Schwenk.⁴³⁴ A signal-to-noise ratio of 30 was achieved in a measuring time of 2 h. In order to improve the performance, Schwenk⁴³⁵ developed a variant of this pulse scheme, *Quadriga Fourier Transform*, using four measurements with different frequencies of the applied rf pulses, and obtained from $\text{Fe}(\text{CO})_5$ a ^{57}Fe resonance with a signal-to-noise ratio of 100 by applying over 6 million pulses in 20 h. In a subsequent study, two NMR spectrometers were combined by Sahm and Schwenk,⁴³⁶ and a special probe assembly was constructed in order to enable simultaneous measurement of signals of ^2H and a nucleus such as ^{57}Fe with a small magnetic moment.

Haslinger et al.⁴³⁷ studied the ^{57}Fe NMR spectra of 20 ferrocene derivatives at natural abundance by conventional FT techniques, and Jenny and von Philipsborn⁴³⁸ examined the spectra of 35 organo-iron complexes, predominantly of the type $[\text{Fe}(\text{CO})_3(\text{diene})]$, and obtained a chemical shift range of 3000 ppm. The ^{57}Fe shieldings were discussed in terms of charge distribution in the complexes. In 1984, Baltzer et al.⁴³⁹ reported a much larger chemical shift range in porphyrins and some coordination compounds. They also studied the magnetic field dependence of T_1 , and concluded that chemical shielding anisotropy provides the principal mechanism for relaxation at superconducting fields.

Mann⁴⁴⁰ found that the one-bond coupling constants of ^{57}Fe to ^{13}C and ^{31}P in iron pentacarbonyl and in iron phosphine carbonyls span the range of ca. 23–32 Hz, whereas in ferrocene compounds they are much smaller (2–7 Hz). A value of about 8 Hz for the one-bond ^{57}Fe – ^{15}N coupling has been obtained by Morishima et al.⁴⁴¹

In 1985, two groups reported almost simultaneously the first studies of ^{57}Fe NMR in a protein, carbonmonoxymyoglobin. Both Oldfield and co-workers⁴⁴² and Baltzer et al.⁴⁴³ used enriched samples and unusual spectrometer arrangements, in which the sample tube was transverse to the axis of the superconducting solenoid, in order to take advantage of the higher sensitivity of a solenoidal, rather than a saddle-shaped receiver coil. Even then a long scan was required, as illustrated in Figure 63. Both groups reported relaxation times, from which they deduced values of the chemical shielding anisotropy.

The only magnetically active isotope of nickel is ^{61}Ni , with a natural abundance of 1.19%, a sensitivity only 0.4% as great as ^1H , and a nuclear spin of $\frac{3}{2}$. These unfavorable

Figure 63 The 16.3 MHz ^{57}Fe NMR spectrum of carbon monoxymyoglobin, enriched to 90% in ^{57}Fe , 1 mL sample, 10 mM. Total experimental time: 10 h⁴⁴³

factors are responsible for the fact that ^{61}Ni has received very little attention. After the first report on ^{61}Ni NMR in $\text{Ni}(\text{CO})_4$ by Drain⁴⁴⁴ in 1964, over 15 years elapsed before Schumann et al.⁴⁴⁵ and Hao et al.⁴⁴⁶ studied a number of nickel complexes in order to establish the ranges of chemical shifts, coupling constants, relaxation times, and linewidths. In the cases investigated, the chemical shift range was about 1000 ppm, linewidths ranged from 4–90 Hz, one-bond ^{61}Ni – ^{31}P couplings were found to lie between 398 Hz and 482 Hz, and a two-bond ^{61}Ni – ^{19}F coupling constant was determined as 28 Hz.

Alkali and Alkaline Earth Nuclei

All these nuclei possess quadrupole moments, but that of ^6Li is extremely small, as we discuss later. Except for some compounds of lithium, beryllium, and magnesium, these elements are generally found in ionic form, so quadrupole coupling constants are often sufficiently small to give lines of only moderate width. For ^7Li , linewidths of less than 1 Hz (compared with typical linewidths of about 150 Hz for ^{85}Rb and ^{87}Rb) were observed by Hartwell and Allerhand.⁴⁴⁷

The first report on NMR shifts in alkali metal ions was made by Gutowsky and McGarvey⁴⁴⁸ in the solid state as early as 1953. This was, in fact, the first publication on shifts in compounds for which the binding is ionic. The shifts of ^{87}Rb and ^{133}Cs in the halides were measured with reference to saturated aqueous solutions of the respective chlorides. The sample and reference were placed in adjacent coils in two separate rf bridge systems. The narrow resonance of the reference was displayed on an oscilloscope, while the broad resonance from the solid halide was detected with a narrow-band amplifier.

In 1956, Wertz and Jardetzky⁴⁴⁹ carried out the first investigation of ^{23}Na in aqueous solution. They were unable to observe any change in chemical shift with various anions, but found considerable variation in the linewidths. They attributed the broadening to quadrupolar interactions that reflected departures from the effectively spherical symmetry of charge distribution around the sodium nucleus, such as would occur in ion pair or complex formation. This work established the basic pattern for further observations of alkali

and alkaline earth nuclei in aqueous solution, in which the useful information comes primarily from the linewidth changes that accompany alterations in the quadrupole coupling constant rather than from chemical shift variations. However, the large chemical shift range in cesium (about 120 ppm) has been exploited in many studies.

Aqueous Na^+ interactions with salts of organic acids have been investigated since the 1950s, as have interactions with sugars and with esters of phosphoric acid. ^7Li interactions with DNA bases and nucleosides in DMSO have been studied by Plaush and Sharp.⁴⁵⁰ Alkali ion NMR has developed into a powerful tool for studies of alkali ion coupling with ionophores. It has been employed extensively in the study of the thermodynamic stability, dynamics, and kinetics of such complexes.

A large number of nonaqueous solutions have also been investigated. The first systematic study on the applicability of alkali ion NMR in nonaqueous environments was conducted in 1966 by Maciel et al.,⁴⁵¹ who determined the ^7Li chemical shifts of LiBr and LiClO_4 in 11 simple organic solvents and discussed the origin of the chemical shift differences. The work of Bloor and Kidd (1968) on NaI in several organic solvents stimulated keen interest in using ^{23}Na NMR in nonaqueous systems.⁴⁵² The ^{39}K chemical shifts of KI in ethylenediamine and of KOH in CH_3OH were studied by Sahm and Schwenk,⁴⁵³ and later by Shih and Popov,⁴⁵⁴ who presented an extensive report on the concentration and counterion dependence. Halliday et al.^{455,456} have made extensive studies on ^{133}Cs chemical shifts.

^6Li has such a small quadrupole moment that it behaves more like a spin- $\frac{1}{2}$ nucleus, and it should afford narrow lines irrespective of the symmetry of the field gradient at the site of the nucleus. Surprisingly, ^6Li high-resolution NMR in solution was first observed as late as 1976 by Felix Wehrli,⁴⁵⁷ who describes the experiment in his historical sketch (**Wehrli, Felix W.: From Carbon-13 to Quadrupolar Nuclei NMR and Medical Imaging --Reflections**)

Upon dialing the frequency of ^6Li , to my delight a signal crept across the oscilloscope. However, I was unable to reproduce the finding and aborted the experiment after a while. The elusive signal reappeared in a second attempt several hours later, at which time I became certain that the observation was real. The culprit for the apparent irreproducibility, of course, was the exceedingly long T_1 In D_2O , T_1 was found to rise up to 17 min at 80°C !

Organic compounds involving covalent lithium–metal bonding, such as C–Li in alkyllithium compounds, were subjected to investigations beginning in the early 1960s.^{458,459} The studies provided valuable information on the structure and dynamic properties of these compounds, primarily through observations of spin–spin coupling. For example, methyl-lithium was found to be a tetramer based on a tetrahedral arrangement of lithium atoms, with the carbons placed symmetrically above each face of the tetrahedron and bonded to all three adjacent lithium atoms.⁴⁶⁰

From the NMR standpoint, the situation for the alkaline earth nuclei is not as bright as that of the alkali metals. The only nucleus with reasonable sensitivity is ^9Be . Barium has two NMR-sensitive isotopes, both with large quadrupole moments and extremely large quadrupole relaxation broadening. The relaxation times of ^{25}Mg and ^{43}Ca ions, as observed by Lindman et al.⁴⁶¹ in 1977, are reasonable (0.15 s for free

Mg^{2+} and 1.3 s for Ca^{2+}) but the sensitivities of both nuclei are extremely low. Since these factors put more stringent demands on spectrometer sensitivity, even high-precision measurement of the magnetic moments in these nuclides had to wait until the 1970s when they were made by the Tübingen group of Otto Lutz (^{43}Ca and ^{87}Sr in 1973,^{462,463} ^{25}Mg in 1975,⁴⁶⁴ and ^{135}Ba and ^{137}Ba in 1977–78^{465,466}).

Like the alkali ions, the chemical shift range in the alkaline earth ions increases with atomic number, and the solvent dependence of chemical shifts is also similar to that of the alkalis. Again, linewidth changes on complexation of alkaline earth nuclei have provided the most useful information for metal ion–ligand interactions. Tetrahedral solvates of the beryllium cation with trimethyl phosphate and other ligands have been examined by Delpuech et al.,⁴⁶⁷ and the kinetics of the exchange studied from the lineshape analysis of the temperature-dependent ^9Be spectra. Bryant⁴⁶⁸ derived exchange rates for adenosine triphosphate (ATP) binding to Mg^{2+} from the temperature dependence of the ^{25}Mg linewidth in the presence of excess magnesium chloride. A linear dependence of the ^{43}Ca relaxation time in aqueous Ca^{2+} -ATP solutions has been interpreted in terms of exchange between free and bound calcium ions,⁴⁶⁹ the Ca^{2+} binding being with the phosphate portion of the ATP molecule.

Organometallic compounds of beryllium and magnesium have been investigated with the help of ^9Be and ^{25}Mg NMR studies. Kovar and Morgan⁴⁷⁰ studied a wide range of organoberyllium compounds and reported chemical shifts, linewidths, and spin–spin coupling constants. The beryllium coordination number was found to have a great effect on the chemical shift as well as the linewidth. The chemical shift is higher and the linewidth is much larger (over an order of magnitude) for three-coordinate than for four-coordinate beryllium. Spin–spin couplings of ^9Be with ^{19}F and ^{31}P were observed. In the BeF_4^{2-} ion, $J_{\text{Be–F}}$ was found to be 34 Hz and in tetrahedral organophosphorus complexes a two-bond Be–P coupling of 4–6 Hz was observed by Delpuech et al.⁴⁶⁷ The small values were attributed to the strongly ionic character of the beryllium compounds. Wehrli⁴⁷¹ employed a combined ^9Be and ^{13}C relaxation experiment to determine the ^9Be quadrupole coupling constant in bis(acetylacetonato)beryllium.

Solid state NMR studies of the alkaline earths are much older than chemical applications. They started as early as 1953 with Knight shift studies⁴⁷² in beryllium and are essentially restricted to Knight shifts, relaxation times, and quadrupole coupling constants. ^{87}Sr NMR was used by Weber and Allen⁴⁷³ in 1963 to study phase transitions in SrTiO_3 .

The Halogens

Unlike ^{19}F , which has a spin of $\frac{1}{2}$, the other halogens have large quadrupole moments whose presence has virtually precluded high-resolution studies of their resonances in covalent compounds. Most investigations have concentrated on halide anions or other highly symmetric ions such as perchlorate, with information coming primarily from linewidths or T_1 measurements. Sensitivities and natural abundances for several isotopes of chlorine, bromine, and iodine are reasonably satisfactory so as to enable studies in concentration ranges appropriate both to chemical and biological problems.

Figure 64 The 7.23 MHz ^{35}Cl spectrum of chlorodimethylsilane in pentane. This continuous wave spectrum used a substitution of a perchloric acid sample during the scan for external referencing, with a 2016 Hz modulation sideband for calibration

^{35}Cl and ^{37}Cl chemical shifts in concentrated hydrochloric acid, barium perchlorate, and perchloric acid were first measured by Proctor and Yu⁴²² as early as 1951. For both isotopes, they observed that the resonances in perchloric acid were displaced to lower fields by about 900 ppm relative to the resonances in hydrochloric acid. Subsequently, chemical shift measurements of ^{35}Cl , ^{81}Br , and ^{127}I in aqueous solutions of HCl, HBr, and HI were carried out by Masuda and Kanda⁴⁷⁴ in 1954. The signals were found to shift to lower fields with increasing concentration due to the presence of undissociated species or some kind of ion pairs.

The use of ^{127}I NMR to investigate the kinetics of the triiodide equilibrium was demonstrated by Myers⁴⁷⁵ in 1958. Changes in the linewidth were employed to compute the rate constants of the reaction. Thus, in the 1950s the stage was set for the use of halide ion NMR to obtain a detailed insight into a number of structural and dynamic features of electrolyte solutions, such as solvation, preferential solvation in mixed solvents, and ion–ion distribution in ion pairing. Major contributions to this field of research have been made by H.G. Hertz and co-workers who have performed both experimental and theoretical investigations for over 20 years.

A major application of halogen NMR involves the study of solutions of amphiphiles, proteins, and polyelectrolytes, where quadrupole relaxation is very sensitive to ionic interactions. Halogen quadrupole relaxation has become a standard method for the study of anion binding to proteins.

In covalent compounds, on the other hand, ^{35}Cl linewidths are so great that only low precision can be obtained in the experimental determination of chemical shifts, and the situation is virtually hopeless for bromo and iodo compounds. Bernd Wrackmeyer in his sketch (*Wrackmeyer, Bernd: A Personal Retrospect of Multinuclear Magnetic Resonance in Liquids*) provides an example, reproduced in Figure 64, which contrasts the sharp line from the tetrahedral ClO_4^- ion with that in a less symmetric compound, which has a linewidth of more than 2 kHz. Although improved techniques and much higher magnetic fields have alleviated the problems seen in this early CW study, only few data are available for covalently

bound ^{35}Cl . The reported values indicate a range of about 1000 ppm.

Some Heavy Metal Nuclides

^{203}Tl and ^{205}Tl are among the most sensitive NMR nuclides and were investigated quite early. Because of its 70 % isotopic abundance, ^{205}Tl has been commonly selected for study. By 1953, both solid- and liquid-state spectra for thallium had been obtained by Bloembergen and Rowland,⁴⁷⁶ and by Gutowsky and McGarvey,⁴⁷⁷ respectively. The chemical shift range is about 7000 ppm for Tl(III) and 3400 ppm for Tl(I) compounds, a factor that has made ^{205}Tl NMR useful in many studies, including those in which Tl^+ can be substituted for an alkali cation in studies of ion transport across membranes, and activation and regulation of enzymes. For solid state studies, CP MAS and related techniques have been employed.

^{195}Pt is one of the easiest heavy nuclei to observe by NMR and was initially studied by Proctor and Yu,⁴²² who measured the magnetic moment with a 1.0 M solution of H_2PtCl_6 . However, little work was done until the late 1960s when Pidcock, Richards, and Venanzi⁴⁷⁸ and Zelewsky⁴⁷⁹ studied several Pt(II) and Pt(IV) complexes, and demonstrated the use of ^{195}Pt NMR for the study of bonding characteristics in platinum complexes. The chemical shift range is about 15 000 ppm. Spectra of chloro–bromo complexes of Pt(IV) were used to estimate the relative stabilities of the complexes, and the applicability in the determination of equilibrium constants of platinum compounds was pointed out.

Although the potential was fully realized from these studies, interest in widespread applications did not pick up until the 1970s when FT methods permitted study of small amounts of expensive platinum compounds. ^{195}Pt coupling constants have been found to be of great interest in structural studies. Values reaching 30 kHz were observed by Ostojka-Starzewski and Pregosin⁴⁸⁰ in 1980.

The first high-resolution ^{113}Cd spectrum was obtained by Maciel and Borzo⁴⁸¹ in 1973, and two other trend-setting papers dealing with the general applications of ^{113}Cd NMR were published a few years later by Kostelnik and Bothner-By⁴⁸² and by Ellis and co-workers.⁴⁸³ Spin–lattice relaxation times were typically of the order of a few seconds. The high sensitivity of the chemical shift to structural changes has made ^{113}Cd a promising nucleus for biological applications, especially in metalloproteins as a substitute for zinc or calcium, which are very difficult to study by NMR. Spin–spin coupling to nuclei such as ^{13}C , ^{15}N , and ^{31}P has been found to be quite large and sensitive to the type of binding. Applications of ^{113}Cd NMR both in the solid and the liquid states have been employed in molecular structure and anisotropic motion studies of cadmium-substituted porphyrins by Ellis et al.⁴⁸⁴

^{119}Sn , and to some extent ^{117}Sn , has been studied by several groups. Lauterbur and Burke in 1958 were the first to report chemical shifts in tin compounds at 8.5 MHz.^{485,486} Depending upon the spin–lattice relaxation times, the spectra were recorded as rapid or slow passage signals in dispersion or absorption modes. ^{119}Sn has been found to be very useful in the study of redistribution reactions in mixtures of stannic halides and other tin compounds. A good illustration, from the historical sketch by Bernd Wrackmeyer, (*Wrackmeyer, Bernd: A Personal Retrospect of Multinuclear Magnetic Resonance*

Figure 65 The 74.6 MHz ^{119}Sn spectrum of an equilibrated mixture resulting from the exchange reaction between $(\text{Me}_2\text{SnSe})_3$ and $(\text{Ph}_2\text{SnS})_3$. In this ^1H -decoupled spectrum, a large number of satellite peaks arising from ^{117}Sn and ^{77}Se can be seen

in Liquids) is shown in Figure 65 where 39 out of 40 possible lines are observed.

An overall chemical shift range of about 3000 ppm has been observed in most tin compounds, with a very strong solvent dependence of the shifts due to coordination with the solvents. Solid state ^{119}Sn was pioneered by Lippmaa et al.³⁹⁰ and has been pursued extensively by Robin Harris and co-workers in investigating insoluble organotin compounds.

The chemical shifts of ^{207}Pb , first measured by Piette and Weaver⁴⁸⁷ in 1958, range over 16 000 ppm. In ionic compounds the resonance is shifted to high field, whereas in compounds involving some covalent bonding it is shifted toward lower fields. The one-bond Pb-H coupling constant was found to be about 2400 Hz,⁴⁸⁸ and couplings with many other nuclei such as ^{14}N , ^{15}N , ^{13}C , ^{31}P , ^{11}B , and ^{19}F have been measured.

After the first observation of ^{199}Hg NMR in 3.5 M $\text{Hg}_2(\text{NO}_3)_2$ by Proctor and Yu⁴⁸⁹ in 1951, ^{199}Hg chemical shifts in a series of dialkylmercury compounds were measured by Dessy et al.⁴⁹⁰ in 1959. The overall chemical shifts of ^{199}Hg were explained by Schneider and Buckingham.⁴⁹¹ ^{199}Hg lines are usually broad because of scalar couplings and exchange.

Although ^{109}Ag is the most favorable NMR isotope of silver, it has low sensitivity, long spin-lattice relaxation times, and a negative NOE. A value of more than 1000 s for the T_1 of ^{109}Ag in $\text{AgNO}_3/\text{D}_2\text{O}$ solution was measured by Kronenbitter, Schweizer, and Schwenk⁴⁹² in 1980 using

steady-state techniques. Most available ^{109}Ag data refer to labile species, but some results for nonlabile complexes have been reported by van Koten and co-workers.⁴⁹³

For a number of years, the direct observation of ^{103}Rh NMR was restricted to rhodium metal and intermetallic compounds.⁴⁹⁴ Studies of a few coordination complexes of ^{103}Rh using indirect double resonance techniques were also available^{495–497} prior to 1979, when the first direct high-resolution observation of ^{103}Rh NMR was reported by Gansow and co-workers.⁴⁹⁸ ^{103}Rh was the only spin- $\frac{1}{2}$ nucleus which had remained unstudied directly by high-resolution NMR in organic systems until that time. The initial spectra were recorded by time-averaging of free induction decays in highly concentrated samples ($\sim 2\text{M}$) for 10 h with 20 mm sample tubes and using relaxation agents for some samples. In 1980, the efficiency was improved by using the Quadriga FT method to obtain a signal-to-noise ratio of 100:1 in 2 h without a relaxation agent.⁴⁹⁹ Cocivera et al. were subsequently able to obtain a spectrum of a 0.25 M solution of $\text{Rh}(\text{acac})(\text{CO})_2$ in 1 min.⁵⁰⁰

Rhodium(III) gives a much larger chemical shift range than Rh(I), about 12 000 ppm. Values of T_1 vary from a fraction of a second to a few tens of seconds. Coupling constants with various nuclei up to about 200 Hz have been observed.

Like rhodium, ^{183}W has been difficult to observe directly because of low sensitivity, and most of the information has been obtained indirectly from double resonance techniques.

The first direct measurement of tungsten was made on solid WO_3 by Narath and Wallace⁵⁰¹ and in liquids (WF_6 , WCl_6 , and simple WO_4^{2-} ions) by Banck and Schwenk,⁵⁰² who used the Quadriga FT technique. The first direct observation of ^{183}W for more complex heteropoly- and isopolytungstates was made by Acerete, Hammer, and Baker⁵⁰³ in 1979.

^{183}W chemical shifts are very sensitive to structural change, with a difference of about 1200 ppm between the oxidation states W(VI) and W(0). Coupling constants with phosphorus have been most extensively studied, and the values spread over a wide range from about 10–500 Hz for one-bond couplings. Values of T_1 are more difficult to obtain due to low sensitivity, but a typical value of 4.2 s has been observed in WF_6 by Banck and Schwenk.⁵⁰²

Other Important Nuclides

^{27}Al chemical shifts and Al–H coupling in LiAlH_4 were measured first by O'Reilly⁵⁰⁴ as early as 1960. The ^{27}Al – ^1H coupling was found to be 110 Hz. ^{27}Al has a chemical shift range of nearly 450 ppm. The shifts can be classified according to the ligand symmetry about the aluminum ion, those with octahedral symmetry appearing at the highest field, those with tetrahedral symmetry in an intermediate range, and alkylaluminum compounds and their adducts at the lowest field.

^{27}Al NMR has been used to investigate the physical and chemical properties of aqueous solutions of aluminum salts. For example, Akitt et al.⁵⁰⁵ determined the hydration number of the Al^{3+} ion, while both the Akitt and Lutz groups^{506–508} studied the hydrolysis, polymerization, and complexation of Al^{3+} . Solvation and complexation in nonaqueous and mixed aquo–organic solvent systems have also been investigated by numerous workers from 1967 onwards.^{509–516} The Al^{3+} ion can interact quite strongly with basic solvent molecules and under favorable conditions scalar couplings between ^{27}Al and the nuclei of the solvent molecules have been observed. In some mixed solvents, the ligand exchange rate is slow enough to permit the observation of several solvated species, thus enabling the determination of kinetic and thermodynamic parameters.

Solid state NMR has also been employed for the study of ^{27}Al NMR. Special aluminum-free probes are now commercially available in order to avoid interferences from the signal coming from the probe material. It is possible to distinguish octahedral and tetrahedral aluminum environments, since aluminum in symmetrical sites produces noticeably narrowed lines in MAS experiments. Merryman et al.⁵¹⁷ confirmed the presence of AlCl_4 in solid samples prepared from mixtures of AlCl_3 , ICl , and I_2 . Resing et al.⁵¹⁸ used ^{27}Al NMR to study zeolites, while Mueller et al.⁵¹⁹ were able to distinguish between six- and four-coordinate aluminum in a variety of solids.

The ^{33}S nucleus has a small magnetic moment, a spin of $\frac{3}{2}$ and a natural abundance of only 0.76%. The spectral lines are typically several hundred Hz wide except in the most symmetric compounds with tetra-coordinate hexavalent sulfur. In 1972, Retcofsky and Friedel⁵²⁰ obtained ^{33}S chemical shifts in 13 different compounds and found a chemical shift range of 650 ppm, with linewidths ranging from 61 Hz to 9000 Hz. NMR data on ^{33}S were obtained in the dispersion mode

NMR DISCUSSION GROUPS IN GERMANY, FRANCE, ITALY, AND JAPAN

Several national discussion groups on magnetic resonance are well known.

Fachgruppe Magnetische Resonanzspektroskopie

A German NMR Discussion Group was formed in 1974 at the initiative of Ernest Lustig, who had recently returned to Germany from the U.S. Others active in the initial organization were Gerhard Binsch, Eberhard Breitmaier, Ludger Ernst, Harald Günther, Horst Kessler, Robert Kosfeld, Dieter Leibfritz and Adalbert Mannschränk. By 1978, at the fifth annual meeting, the group became a division of the German Chemical Society, broadened its scope to ESR as well as NMR, and adopted its current name. The annual meetings generally attract 200–300 participants.

Groupe d'Etude de Résonance Magnétique (GERM)

This French discussion group was founded in 1976 and held its first meeting the next year in Vichy. Subsequently, annual meetings were held until 1985, when a biennial format was adopted for the general meeting, with smaller specialized meetings in the intervening years.

Gruppo di Discussione Delle Risonanze Magnetiche

Founded in 1974 in Milan, the Italian group includes discussions on both NMR and ESR. Initially two meetings per year were held, but there is now an annual meeting of 2–3 days. The group includes chemists, physicists, and biologists.

Research Group of NMR in Japan

The formation and activities of this group and others in Japan are covered in the historical sketch by I. Ando.

until 1973 when Lutz et al.⁵²¹ employed Fourier transform methods to study natural abundance ^{33}S and accurately determine the magnetic moment. The only coupling constant of ^{33}S reported is the one-bond $J_{\text{S-F}}$ in SF_6 , of 251 Hz.⁵²¹ Some natural abundance ^{33}S studies have been applied to chemical problems but generally have been found to be feasible for only a few specific applications.⁵²²

The ^{51}V nucleus has a quadrupole moment, but in many of its complexes exhibits rather narrow lines. In 1965, Howarth and Richards⁵²³ established ^{51}V NMR as an excellent tool for the characterization of the pH-dependent species existing in aqueous solutions of vanadates. The ^{51}V chemical shifts in various oxidation states have been studied extensively in a host of derivatives— VO^{3+} by Howell and Moss⁵²⁴ and Rehder,⁵²⁵ iso- and heteropolyanions of V(V) by Kazanskii and Spitsyn⁵²⁶ and O'Donnell and Pope,⁵²⁷ and a series of vanadium carbonyl compounds by Rehder et al.^{528–530} The chemical shift range is about 2000 ppm, except for $[\text{V}(\text{CO})_6]^-$ in MeCN solution for which a value of 5660 ppm was reported.⁵³¹ The studies demonstrate the existence of discrete chemical shift ranges for vanadium in different oxidation states. The lowest oxidation state is most highly shielded and ^{51}V becomes progressively deshielded with an increase in the

oxidation state. Hence ^{51}V chemical shifts are diagnostically useful for the characterization of these compounds.

Coupling constants for ^{51}V with ^1H , ^{13}C , ^{31}P , ^{19}F , and ^{119}Sn have all been observed. The values range from about 20 Hz for the couplings to protons to about 900 Hz for $J(^{51}\text{V}-^{119}\text{Sn})$. High-resolution ^{51}V NMR spectra of solid vanadium compounds with magic angle or near magic angle spinning were observed by Oldfield et al.^{369,532} in 1982.

The ^{93}Nb nucleus is one of the most sensitive and has been studied fairly extensively. The first high-resolution spectrum was reported in 1963 by Packer and Muetterties⁵³³ of the hexafluoronioate ion, $[\text{NbF}_6]^-$. The results indicated the presence of $[\text{NbF}_6]^-$ ions in solution rather than $[\text{NbF}_7]^{2-}$ ions. Practically all the data on ^{93}Nb deal with compounds in which the ligands are halides or pseudohalides. In these compounds, the shielding decreases with decreasing electronegativity of the halogen. The total chemical shift range observed is about 2400 ppm. Mixtures of NbCl_5 and NbBr_5 in acetonitrile undergo a slow ligand redistribution reaction to give a mixture of products, each of which gives a characteristic ^{93}Nb spectrum.

Most manganese compounds are paramagnetic and are generally not suitable for high-resolution NMR. In 1974, Lutz and Steinberg⁵³⁴ not only provided an accurate value of the ^{55}Mn magnetic moment but also reported the concentration dependence of chemical shift in permanganate for a variety of counterions and found an unusually large deuterium-induced isotope shift of 0.76 ppm. ^{55}Mn chemical shifts cover a range of 3000 ppm, with the shielding increasing with oxidation state. Linewidths vary from about 10 Hz in KMnO_4 to about 10 kHz in $\text{HMn}(\text{CO})(\text{PF}_3)_4$, thus offering the prospect of determining electric field gradients from linewidths. Coupling constants of ^{55}Mn with other nuclei have been obtained from the resonances of the other nuclei. Burton and Harris⁵³⁵ have deduced from MAS experiments a value of 1.60 MHz for the ^{55}Mn quadrupole coupling constant in a polycrystalline KMnO_4 sample.

Two isotopes of copper, ^{63}Cu and ^{65}Cu , are readily detected by NMR, but ^{63}Cu is the preferred isotope because of better sensitivity, despite marginally larger linewidths. As mentioned in Section 2, the history of NMR in copper starts even before the discovery of the Knight shift in 1950. In the solution state, McConnell and Weaver⁵³⁶ analyzed linewidth measurements in concentrated hydrochloric acid solutions containing both copper(I) and copper(II) chloride to determine the bimolecular rate constant for the electron-exchange process. Fujiwara and co-workers⁵³⁷ also studied an aqueous solution of CuCN and observed marked changes in the ^{63}Cu NMR linewidths with the relative amount of cyanide added, resulting from chemical exchange between the various species $\text{Cu}(\text{CN})_4^{3-}$, $\text{Cu}(\text{CN})_3^{2-}$, and $\text{Cu}(\text{CN})_2^-$. The real problem in the widespread application of ^{63}Cu NMR arises from the fact that Cu(II) is paramagnetic; hence NMR is largely confined to the Cu(I) species, which are less stable and limited in chemistry.

The ^{63}Cu linewidths range between 20–160 kHz. A one-bond $^{63}\text{Cu}-^{31}\text{P}$ coupling of 1210 Hz has been found⁵³⁸ in the phosphine complex $\text{Cu}[\text{P}(\text{OME})_3]_4^+$. The known chemical shift range for Cu(I) is about 500 ppm.

Solid state NMR methods have been applied to ^{63}Cu . Spin-lattice relaxation times and chemical shifts in copper(I) halides were measured in polycrystalline samples by Günther and Hultsch⁵³⁹ in 1969 and subsequently by many other

workers. The use of high-speed MAS for the determination of precise values of Knight shifts of $^{63}\text{Cu}/^{65}\text{Cu}$ in metallic copper was made by Andrew et al.⁵⁴⁰ in 1971. The ^{63}Cu NMR transitions of divalent copper ions were detected for the first time in copper acetate monohydrate by Kawamori and Soda⁵⁴¹ in 1975, and the quadrupole coupling constant was calculated as 117 MHz.

Some Rarely Studied Nuclides

Each of the NMR-accessible nuclides that we have not yet discussed has provided information important to particular applications, but in general has had only limited study. We mention here only some salient points concerning the initial observation of a particular isotope or unusual features that have been observed.

Of the arsenic, antimony, and bismuth group, only antimony has been studied extensively. The first systematic study of ^{75}As chemical shifts was as late as 1977 by Balimann and Pregosin.⁵⁴² Because of quadrupole broadening, the compounds studied were tetra- or hexacoordinated of the pentavalent type. Both ^{121}Sb and ^{123}Sb were among the earliest nuclei to be investigated by NMR. In fact, SbF_6^- was one of the first species for which splittings due to spin-spin coupling constants were observed,^{543–545} although not properly understood at that time. Again, the large magnitude of the quadrupole moment is responsible for the fact that observation of less symmetric species has not been possible. The first chemical shift data were provided by Kidd and Matthews for a series of simple antimony compounds.⁵⁴⁶ The narrowest line observed (~ 300 Hz) was for the SbCl_6^- ion. Despite the fact that the ^{209}Bi in aqueous bismuth nitrate was reported⁵⁴⁴ as early as 1951, the literature seems to be void as far as the chemical applications of ^{209}Bi NMR are concerned.

The ^{45}Sc nucleus is 100% abundant and has very high NMR sensitivity. The precise magnetic moment and the isotope shift of 6.2 ppm for the ^{45}Sc resonance in aqueous ScCl_3 in H_2O and D_2O were measured by Lutz⁵⁴⁷ in 1969. Buslaev et al.⁵⁴⁸ and Melson et al.⁵⁴⁹ have studied ^{45}Sc resonances in a variety of compounds in aqueous and nonaqueous media. However, scandium NMR has not attracted widespread NMR interest thus far.

Both ^{47}Ti and ^{49}Ti have low sensitivity for NMR observation. A unique feature of the two isotopes is the closeness of their resonance frequencies, which differ by just 271 ppm. The only chemically significant data are by Kidd et al.,⁵⁵⁰ who investigated the tetrahalides. A typical spectrum of a mixture of the chloride and the bromide (Figure 66) shows spectra from both isotopes.

Both ^{95}Mo and ^{97}Mo have low NMR sensitivity. The earlier work on molybdates was concentrated on relaxation studies, isotope effects, and medium effects. Vold and Vold⁵⁵¹ determined the relaxation times of $[\text{MoO}_4]^{2-}$ and $[\text{MoO}_4]^{2-}$ as 6.5 and 840 ms, respectively. The unusually large difference of the quadrupole moments of the two isotopes has proved to be of some significance in molybdenum NMR studies. The cation, solvent, and pH dependences of the ^{95}Mo shielding in $[\text{MoO}_4]^{2-}$ have been studied by Kautt et al.⁵⁵² Lutz et al.⁵⁵³ have obtained chemical shift data for several molybdenum compounds and have even observed $^{34}\text{S}/^{32}\text{S}$

Figure 66 The 3.38 MHz ^{47}Ti and ^{49}Ti NMR spectra recorded as derivative signals from a slow passage dispersion mode sweep. The splitting of each resonance is due to overmodulation at 40 Hz.⁵⁵⁰ (Reproduced by permission of the American Chemical Society)

isotope effects on the shielding of the quadrupolar ^{95}Mo in MoS_4^{2-} .

The first measurement of ^{77}Se chemical shifts (for H_2SeO_3 and H_2SeO_4 relative to H_2Se) was made by Walchli⁵⁵⁴ in 1953. The initial studies of ^{125}Te NMR concerned Knight shift investigations by Cabane and Froidevaux⁵⁵⁵ in 1968 and Warren⁵⁵⁶ in 1972. Subsequently, indirect detection of ^{125}Te in several organic compounds was carried out by McFarlane and McFarlane⁵⁵⁷ in 1973. The first high-resolution ^{125}Te NMR study in organic compounds was made only in 1976 by Drakenberg et al.⁵⁵⁸ The overall chemical shift range exceeds 4000 ppm. The existence of ^{123}Te has made it possible to measure Te–Te couplings in symmetric species.

The first article on the solution NMR of ^{53}Cr at natural abundance was by Egozy and Loewenstein⁵⁵⁹ in 1969 and was related to the derivation of the rate constant for the chromate–dichromate equilibrium. Lutz's group reported chemical shift data for the chromate ion as a function of counterion concentration.⁵⁶⁰

Although technetium does not have a stable isotope, radioactive ^{99}Tc , with a half-life of 5×10^5 years, has quite favorable properties for NMR detection—100% natural abundance and a very high sensitivity. In 1981, Kidd⁵⁶¹ observed the ^{99}Tc resonance in $\text{Na}[\text{TcO}_4]$ and obtained the quadrupole coupling constant.

Both ^{185}Re and ^{187}Re have reasonable sensitivity for NMR detection. The $\frac{5}{2}$ nuclear spin and the large quadrupole moments, however, impose problems in their observation. The first study by Dwek, Luz, and Shporer⁵⁶² in 1970 aimed at deriving the quadrupole coupling constant in ReO_4^- . Subsequently, $[\text{ReS}_4]^-$ and $[\text{Re}(\text{CO})_6]^+$ were investigated.^{563,564}

Ruthenium has two NMR active isotopes, namely ^{99}Ru and ^{101}Ru with natural abundances of about 13% and 17% respectively. Both are spin $\frac{5}{2}$ nuclei and have reasonable NMR sensitivities. Only the diamagnetic oxidation states $\text{Ru}(\text{VIII})$, $\text{Ru}(\text{II})$, and $\text{Ru}(\text{0})$ have found interest in NMR. The history of NMR on these nuclei only started in 1981 from work by Brevard and Granger⁵⁶⁵ and Dykstra and Harrison.⁵⁶⁶

Weaver⁵⁶⁷ observed the resonance of ^{67}Zn in 1953, and the first study of ^{67}Zn shielding by high-resolution pulse NMR was made by Epperlein et al.⁵⁶⁸

After the initial observation of ^{113}In and ^{115}In by Proctor and Yu⁵⁶⁹ and several other early papers, the NMR properties of ^{115}In in aqueous and non-aqueous solutions were largely established by the early 1970s.^{570–573} Linewidths were found to be sensitive to environmental symmetry around the indium, and exchange between complexed and free ions has been studied.

An accurate value of the magnetic moment of ^{139}La was reported by Lutz et al.^{465,574} only in 1977–78. The use of direct NMR observation of other lanthanides has been largely restricted to solid state investigations.

The first resonance of ^{89}Y was studied in $\text{Y}(\text{NO}_3)_3$ by Brun et al.⁵⁷⁵ Subsequently, in the late 1970s, several compounds were studied employing improved methodology. In 1971, Kaufmann et al.⁵⁷⁶ were the first to obtain high-resolution ^{73}Ge data on a number of GeR_4 compounds, while a high-precision measurement of the magnetic moment of ^{187}Os was made by Sahm and Schwenk⁴³⁶ in 1974 in Tübingen.

BIOCHEMICAL APPLICATIONS OF NMR

The initial applications of NMR to biochemistry were generally not different in kind from the chemical studies discussed at length in previous sections. But biochemical systems often provided different sorts of challenges and led to the development of new NMR methods. While the distinction between 'chemical' and 'biochemical' is blurred, especially in the early days of NMR, it is convenient and instructive to trace the developments in the biochemical arena.

The first biochemical NMR applications appeared some 40 years ago in an era when neat or saturated solutions were required, instrumental stability was questionable, and effective resolution was extremely limited compared with modern standards. Since then, the history of this field has been shaped by a succession of major technological advances, including greatly improved sensitivity from advances in electronics and probe design, sufficient field/frequency stability to allow multiscan averaging, the development of pulse Fourier transform methods, the availability of high-field superconducting magnets, significant improvements in data handling facilities, and the development of multidimensional NMR. Many of the advances were realized through the intense developmental efforts of commercial NMR instrument companies. Others were individual endeavors with homebuilt systems and combinations of commercial components to overcome 'the technological problems that present the major barrier between creativity and experimental results,' as aptly put by Ad Bax in his historical sketch (*Bax, Ad: NMR of Ethanol and Interferon- γ*).

In this section we outline major milestones in the development of NMR applications to biochemistry in the period from the earliest experiments through the late 1970s and early 1980s, when the development of two-dimensional NMR methods began to make major impacts on the applicability to biopolymers.

Pioneering CW Work at 40 MHz and Below

During the 1950s, NMR was largely a technique in the hands of the organic chemists. Chemical applications of this new

and powerful tool blossomed into many areas, including the study of organic molecules with biological functions. In the latter half of the decade, more complex compounds began to be investigated, and the potential of the technique for applications in biochemistry became apparent. However, the stability, resolution, and sensitivity of the first commercial instruments restricted the types of quantitative information that could be obtained. Early commercial spectrometers were also often equipped only for the observation of protons—the most sensitive naturally occurring NMR nucleus—creating a special challenge to anyone interested in other nuclei (such as ^{31}P). Spectroscopists were compelled to use highly concentrated solutions, since signal averaging had not yet been introduced into NMR. There was also a problem of standards for chemical shift measurements in aqueous (D_2O) solutions. The residual HOD peak was clearly an unsatisfactory standard because its position varied with pH and temperature. Thus spectroscopists typically inserted a small coaxial tube containing a proton-rich substance such as toluene or TMS. In addition to introducing bulk magnetic susceptibility effects, this reduced the effective sample volume and thus the sensitivity. Despite all of these limitations, however, significant early efforts on many fronts demonstrated the feasibility of NMR as a powerful technique to address complex biochemical problems.

Beginning in 1957, exploratory studies were undertaken at 40 MHz on a number of substances of biochemical interest. For example, chemical shift data for concentrated aqueous solutions of common amino acids and several small peptides at different pH values were first reported by Oleg Jardetzky and co-workers.^{577,578} Very shortly thereafter, Bovey and Tiers⁵⁷⁹ published a study of all the common amino acids and several glycyl dipeptides in trifluoroacetic acid (TFA), which happened to be an excellent solvent for both those compounds and the chemical shift standard TMS. The resolution was relatively poor in these early studies, and in many cases the coupling constants were estimated from the peak width at half-height. Chemical shift measurements were tabulated and correlated with molecular structure. Among the more interesting observations in TFA, the diastereoisomers d-leucyl-l-tyrosine and l-leucyl-l-tyrosine could be distinguished by an upfield shift in the methylene peaks of the dl isomer.

As we saw in Section 3.6, by 1958 Lemieux and others had found that the magnitude of vicinal proton coupling constants depended on molecular conformation, and a year later Karplus provided a theoretical treatment of the effect. This information became available at the time the first proton NMR studies of nucleic acid bases, nucleosides, and nucleotides were being undertaken at 40 MHz by Oleg and Christine Jardetzky.^{580–582} Thus, in addition to documenting the pH-dependence of the chemical shifts in concentrated solutions of these substances, the ribose conformations were estimated from the magnitude of the vicinal couplings between H-1' and H-2'. These early studies were hampered by poor resolution and the complications of overlapping lines and strongly coupled spin systems. Complete analyses of nucleoside and nucleotide spectra became possible only at higher fields as discussed in a following section. The 1960 studies also noted a large dependence of the chemical shifts of purine protons on concentration, the beginning of what would eventually become a number of quantitative investigations of the vertical stacking of purines and the effect of ring currents on chemical shifts in neighboring molecules.⁵⁸³

The first theoretical estimations of the chemical shift effects of ring currents in purines and pyrimidines were made by Giessner-Pretre and Pullman,⁵⁸⁴ who extended the calculations of Johnson and Bovey. Their results were later published as isoshielding curves for protons located $\pm 3.4 \text{ \AA}$ from the plane of adenine, guanine, cytosine, or uracil.⁵⁸⁵ These computations and subsequent refinements by these and other researchers were frequently used in the interpretation of ^1H NMR spectra of di-, oligo-, and polynucleotides.

In 1959, Hopkins and Bernstein published a 40 MHz 'introductory study' of fatty acids, fatty acid esters, and natural glyceride oils in chloroform solution 'at sufficiently high concentration to give signals of moderate intensity', i.e. about 200 mg in 0.5 mL.⁵⁸⁶ The authors identified characteristic chemical shifts and were able to estimate the ratios of saturated/monoene/diene fatty acid components in several natural oils (cocoa butter, cottonseed oil, and tung oil).

Explorations at 40 MHz were not limited to small molecules. In 1957, Saunders, Wishnia, and Kirkwood published the first spectrum of a protein, bovine pancreatic ribonuclease.⁵⁸⁷ The choice of ribonuclease, a relatively small protein of molecular weight 13 000, was based on practicality: the protein is quite soluble and was available in sufficient quantity for NMR experiments from Saunders' colleagues at Yale. After failing to obtain any spectrum from the protein in H_2O , Wishnia and Saunders repeatedly lyophilized the sample from D_2O and dissolved it in D_2O to obtain the spectrum shown in Figure 67. This spectrum, which is an NMR classic, began an area of research that has now resulted in structural analyses that rival the accuracy of X-ray crystallography, as we shall discuss in Section 14. From the perspective of the 1990s, the spectrum appears bereft of information, with only four broad peaks resolved. However, at the time, it was exciting and revealing, as recounted by Martin Saunders in his historical sketch (*Saunders, Martin: The First NMR Spectrum of a Protein*):

What did we learn about proteins from this spectrum? The most important thing was that one could obtain a spectrum where aliphatic, aromatic and NH (as they were exchanged out) were roughly at the chemical shifts expected from those found in smaller compounds and that their peaks were fairly sharp. From diffusion and viscosity data, Kirkwood could estimate the correlation time for rotation of the protein molecules. We concluded that, if the molecules rotated as rigid bodies, there would be much more broadening from dipole-dipole interaction than we saw in the spectrum. The relative sharpness of the peaks seemed to imply that there was internal motion.

The Jardetzky's, who had their amino acid data in hand by this time, took the interpretation a step further by demonstrating that the general shape of the observed ribonuclease spectrum could be predicted from the sum of the amino acid constituents.⁵⁸⁸

During the next few years, several additional 40 MHz protein spectra were published, the most revealing of which were those obtained under conditions designed to unfold the native structure.^{589,590} Although detailed information on the native structure was not discernible from these spectra, the denaturation experiments demonstrated that the elimination of secondary and tertiary structure significantly sharpened spectral lines, resulting from a decreased chemical shift dispersion and from increased mobility of the polypeptide chain.

The first NMR spectra of a synthetic polypeptide, poly- γ -benzyl-L-glutamate, were published in 1959 at 40 MHz.⁵⁹⁰

Figure 67 Proton NMR spectrum at 40 MHz of ribonuclease in D_2O .⁵⁸⁷ (Reproduced by permission of the American Chemical Society)

This study, and a succession of later papers on this and related systems, focused on the spectral differences observed as the polypeptide converts from the random coil form (exhibited in solvents such as trifluoroacetic acid) to an α -helical form (in inert or weakly hydrogen-bonding solvents such as chloroform or trichloroethylene). The interest in using NMR to study α -helix to random coil transitions really began in earnest in the late 1960s, with so many publications appearing that Frank Bovey would comment in his 1972 book, *High Resolution NMR of Macromolecules*,⁵⁹¹ ‘recently the flow of published studies has swelled to near torrential proportions.’

In many of these early examples, as well as in much of the work on steroids, alkaloids, and other classes of compounds discussed in previous sections, the emphasis was on the discovery of chemical shift information and its analysis in terms of structure and configuration/conformation. It took the advent of higher-field instruments and time-averaging techniques, however, to create the experimental environment where complex biochemical molecules could be studied in detail.

Water, Water, All Around

From the very beginning of NMR applications to biochemistry and biology, water played an ambiguous role: both a blessing and a nuisance. At 110 M in protons, this ubiquitous constituent of biological systems produced an intense signal and was thus a natural for observation by NMR, as recounted below. On the other hand, it quickly became clear that if one wanted to observe anything other than water protons in an aqueous solution, it was a distinctly unfriendly solvent for 1H NMR. Solution in D_2O , usually after repeated lyophilization of the sample from D_2O to remove water of hydration and exchangeable protons, became the norm, but even then the residual HOD peak often dominated the spectrum. Other than optimizing experimental conditions and avoiding scanning through the HOD signal, this problem could not really be solved until pulse-FT became available and water-suppression schemes were developed.

As early as 1950, Shaw and Elsken measured the intensity of the proton NMR signal at 15 MHz in pieces of apple, potato, and maple wood as a function of water content.⁵⁹² Subsequent studies attempted to correlate signal area and line broadening

with the extent of hydration in a number of substances such as egg albumin, collagen, gelatine, DNA, and solutions of tobacco mosaic virus.^{593–596} Although the interpretation of these early experiments was complicated by instrumental artifacts and arbitrary models that could not be tested, ‘a beginning had been made’, as Oleg Jardetzky put it in his historical sketch (*Jardetzky, Oleg: NMR in Molecular Biology--A History of Basic Ideas*).

In 1957, Davidson and Gold⁵⁹⁷ employed the solvent signal for a different purpose. Recognizing from the classic work of Bloembergen, Purcell, and Pound that paramagnetic ions are effective in relaxing solvent protons, they compared the relative efficiencies of $Fe(H_2O)_6^{3+}$, $Fe^{III}(EDTA)^-$, ferriheme, and ferrihemoglobin for relaxing solvent water protons. Although the results obtained from their 40 MHz saturation recovery and line-broadening measurements were not very accurate, the authors could demonstrate that iron in methemoglobin was less effective than in the small molecules in relaxing water protons. They concluded that the heme group in the protein was relatively inaccessible to bulk solvent protons. Their observations, extended in a subsequent paper by Kon and Davidson,⁵⁹⁸ were followed by a number of later studies focused on sorting out the relative contributions of the possible relaxation mechanisms in a complex system. One additional outcome of this work, suggested in Davidson and Gold’s paper and reported in more detail in a paper by Lumry et al.,⁵⁹⁹ was that the diamagnetic protein itself affected the relaxation rates of bulk solvent water, presumably by slowing the rotational motion of the water molecules as they associated with the much larger biopolymer.

In 1961, Eisinger, Shulman, and Blumberg⁶⁰⁰ used a spin echo apparatus operating at 50 MHz to measure the longitudinal relaxation times of the solvent water signal in solutions of calf thymus DNA to which paramagnetic ions had been added. Bob Shulman recalls the genesis of the experiment in his historical sketch (*Shulman, Robert G.: My Years in NMR*):

The NMR consequence of this interest in biomolecules was that I spoke with Bill Blumberg and Terry Eisinger at Bell Labs who had built a pulsed NMR instrument designed to measure the increased H_2O relaxation they expected to find from free radicals generated during enzymatic reactions. By that time I had shown that the unpaired spins in DNA were from ferromagnetic magnetite inclusions, and I knew that the structure of paramagnetic metal ion binding to DNA was uncertain. If bound outside to the phosphates, the binding efficiency of Mn^{2+} should have been similar to the free ion, while if bound internally, the efficiency should have been reduced from limited H_2O access. We decided to test how the effectiveness of Mn^{2+} as a relaxation agent of the H_2O protons was changed by its binding to DNA. To our surprise, the Mn^{2+} was *more* effective when bound, a phenomenon which we named ‘relaxation enhancement’. We explained it on the basis of the altered correlation time between Mn^{2+} and the H_2O protons which was determined by the rotation time of the $Mn(H_2O)_6$ complex—a rotation time that would be slower when the Mn^{2+} was bound to the DNA molecule, making it more effective as a relaxer. We showed that Co^{2+} and Ni^{2+} , with very short electronic T_1 values, did not give this enhancement when bound to DNA, since the rotational time was shunted by the faster electronic relaxation.

A note on the work appeared in 1961,⁶⁰⁰ and detailed studies were published the following year.⁶⁰¹ Figure 68 shows one illustration of the dramatic effects caused by the

Figure 68 Variation of the proton T_1 value in water as paramagnetic Mn^{2+} ions are added alone or in the presence of varying concentrations of DNA.⁶⁰⁰ (Reproduced by permission of Macmillan Magazines Ltd)

combination of macromolecules and paramagnetic ions. The first application of relaxation enhancement as a sensitive probe for the study of enzyme–metal–substrate complexes was also published in 1962 by Cohn and Leigh.⁶⁰² Working with Leigh's homebuilt pulse spectrometer, they observed large relaxation enhancements in tertiary complexes of enolase and creatine kinase with $Mn(II)$ and substrate. They found that the metal ion bound directly to enolase but the binding to creatine kinase involved an $Mn(II)$ –substrate–enzyme bridge structure. This work attracted Albert Mildvan to Cohn's laboratory, where he obtained complementary NMR and ESR relaxation enhancement data in $Mn(II)$ –bovine serum albumin solutions in order to establish relaxation enhancement as a quantitative tool for determining association constants and exploring the structure of the binding site. The historical accounts of Cohn (Cohn, Mildred: *Peregrinations of an Enzymologist in NMR*) and Mildvan (Mildvan, Albert S.: *Early Applications to Enzymes of Paramagnetic Effects on Nuclear Relaxation*) summarize their investigations in the 1960s and 1970s, undertaken to explain the physical basis of the enhancement and to use the technique to elucidate enzyme mechanisms. In their hands, and those of many other investigators, relaxation enhancement was used to study the structure and dynamics of a wide variety of metal ion–biopolymer complexes including lanthanide-substituted systems.^{603–606} The technique was also extended from the observation of the water proton signal to studies of the substrate itself, using other nuclei such as ^{13}C , ^{19}F , and ^{31}P . A particularly interesting example from the early 1980s, that of the Mn^{2+} derivative of carbonic anhydrase, is provided by J. J. Led (Led, Jens J.: *Aspects of NMR Studies of Paramagnetic Metal Complexes of Biological Relevance. A Historical Sketch*). In this system, sets of complementary magnetization transfer ^{13}C spectra of the substrates CO_2 and HCO_3^- with and without the enzyme allowed the independent determination of relaxation and catalytic exchange rates, and verification of the structure of the metal complex in the catalytic pathway.⁶⁰⁷

During the 1970s and 1980s, attention was placed on quadrupolar nuclei for studies of water in protein solutions, since the interpretation of relaxation measurements using water isotopically enriched with deuterium and/or ^{17}O is simplified by the dominance of the nuclear electric quadrupole interaction. Of the two isotopes, ^{17}O avoided the complication of exchange with ionizable groups and, due to the strong quadrupolar interaction, permitted studies at lower protein concentrations as exemplified by the work of Halle et al.⁶⁰⁸

Full analysis of the relaxation data from both diamagnetic and paramagnetic systems depended on the measurement of relaxation rates as a function of frequency and temperature. This prompted the development of specialized instruments, given the name 'relaxometers' by one of the champions of this approach, Seymour Koenig. The measurement of solvent relaxation has become an extremely important area for research in modern NMR, particularly with the advent of magnetic resonance imaging techniques that contrast different tissues in living systems by sensing the concentration and relaxation of intrinsic H_2O . In the words of Koenig in his historical sketch (Koenig, Seymour H.: *I. I. Rabi, F. Bloch, E. M. Purcell, and the History of NMR and Relaxometry*), 'It remains the best approach for the study of complex macromolecular systems, including tissue.'

Exploitation of True 'High-Resolution' Capability

The introduction of a succession of 60 and 100 MHz instruments in the late 1950s and 1960s resulted in a significant advance in capability, both with respect to increased sensitivity, enhanced field stability and resolution, and the increased spectral dispersion due to the higher field. Improved variable temperature control and multiple resonance techniques became widely available. Although many improvements were focused on 1H NMR, probes for ^{31}P and ^{13}C observation were available, and other 'nonstandard' nuclei of sufficient sensitivity could be studied by those willing to adjust the field strength to match the frequency of an existing probe and rf unit. In 1962, signal averaging was introduced into NMR (Section 5.2) to increase the sensitivity of the NMR experiment and significantly reduce the amount of material required. Even though these advances in instrumentation only partially solved the problems of sensitivity and resolution, they contributed to a substantial increase in the number of NMR applications in biochemistry during the 1960s. As pointed out by Oleg Jardetzky in his historical sketch (Jardetzky, Oleg: *NMR in Molecular Biology--A History of Basic Ideas*), the classes of problems that NMR could solve were clear as early as 1961: '(a) primary structure, (b) conformation or secondary and tertiary structure, (c) rate processes and molecular motion, and (d) interactions between molecules'. These topics largely determined the program for the research of the 1960s, and 'the agenda has remained the same since'.

During the 1960s, extensive compilations of proton chemical shift and coupling constant data were assembled for many of the basic biochemical building blocks, including amino acids and peptides; nucleic acid bases, nucleosides, nucleotides, and oligonucleotides; and monosaccharides.⁶⁰⁹ In addition, as shown by the following examples, ground-breaking work was performed in a number of laboratories to

explore the effects of temperature, pH, neighboring magnetically anisotropic groups, as well as diamagnetic and paramagnetic molecular interactions on chemical shifts and relaxation parameters.

The first study of porphyrins,⁶¹⁰ conducted at 60 MHz in 1959, resulted in the discovery that the NH protons appear as a single resonance, shifted some 13 ppm upfield from a 'normal' position (such as that found in pyrrole), while the bridging methine protons are quite deshielded. The observations, which were explained on the basis of large π -electron ring currents in the macrocyclic rings, foreshadowed interesting later work in heme proteins.

In the early 1960s, several groups investigated hydrogen bonding and base-pairing in nucleosides and nucleotides. Initial studies, using low-temperature experiments on ¹⁵N-enriched 1-methylcytosine in nonaqueous solvents, provided unambiguous proof that the predominant tautomer of cytosine is the amino form and that protonation occurs at N-3.⁶¹¹ Later work on purine and pyrimidine derivatives and nucleosides provided the first NMR confirmation of a Watson–Crick type GC base-pairing.^{612,613}

In 1960, Mildred Cohn and Tom Hughes, then at Washington University, published the first ³¹P spectra of ATP and ADP. Cohn provides a vivid account of these experiments in her historical sketch (*Cohn, Mildred: Peregrinations of an Enzymologist in NMR*), explaining that she had originally thought of NMR in 1955 as a possible means to distinguish the three phosphorus atoms of ATP and thus define the structure of enzyme–metal–ATP complexes. As Washington University's NMR spectrometer was not capable of ³¹P detection, the actual experiment was delayed until she could arrange to accomplish the work at Varian Associates Applications Laboratory during a 1958 summer break spent in California. She used 'three incredibly viscous solutions, 1 M ATP, 1 M MgATP, and 1 M MnATP, the concentrations necessary to observe ³¹P in a single scan at 24.3 MHz in a 5-mm tube.' The spectra showed the expected three peaks, which shifted on complexation with Mg²⁺ and broadened with Mn²⁺.

Cohn extended these original experiments, obtaining higher-resolution spectra (where the P–P coupling could be distinguished as shown in Figure 69), determining the pH dependence of the chemical shifts of ADP and ATP, and studying the effects of metal ions. Early in the metal complex experiments she discovered by accident (as she recounts in her historical sketch) that the effects of Cu²⁺ binding on the ATP spectrum were very different from those of Mn²⁺:

In preparation for the metal complex experiments, I removed the sodium from the commercial ATP and substituted the tetramethylammonium ion on an ion-exchange column. Much to my surprise and chagrin, the spectrum of this preparation differed greatly from that of sodium ATP, the β -P and γ -P resonances were very broad and the α -P resonance was sharper and enhanced in height. Disturbed, I consulted my chemist friends, and Dave Lipkin said, 'It looks like a paramagnetic effect'. Whereupon I investigated the history of the resin and found that it had been sized through a brass sieve, the usual procedure at that time. The unlikely supposition that copper had been picked up by the resin during sizing and had been removed by the ATP was indeed confirmed by ashing the ATP sample and analyzing for copper. Because Cu(II) can only form square planar complexes, only the β -P and γ -P resonances were broadened and the narrowing of the α -P represented the collapse of the unresolved α -P doublet due to the greatly increased relaxation rate of the β -P (the poor man's decoupling technique).

Figure 69 ³¹P NMR spectrum (24 MHz) of adenosine triphosphate (ATP) in water.⁶¹⁴ (Reproduced by permission of the American Society for Biochemistry and Molecular Biology)

This anecdote is interesting historically because it reflects the problems of paramagnetic contamination faced by many early investigators, who sometimes unwittingly drew erroneous conclusions on the significance of line broadenings.

The ATP/ADP results, published in 1960 and 1962,^{614,615} set the stage for the development of an enormous body of literature applying ³¹P NMR to biochemical, biological, and medical problems. In fact, as outlined in Section 12, among the first in vivo NMR experiments were studies of phosphorus-containing metabolites in cells and tissues.

Small linear oligopeptides were initially studied to determine the effect of the peptide bond on amino acid chemical shifts and utilize the information for the analysis of polypeptide spectra. Attempts were also made to see whether chemical shifts could be utilized for primary sequence analysis.^{616,617} The effects were small, however, and the true value of NMR for the study of peptides was found in its ability to probe three-dimensional conformation and the dynamics of these molecules in solution.

A large body of work on synthetic and naturally occurring linear and cyclic peptides was conducted in numerous laboratories during the 1960s and 1970s. For example, Vladimir Bystrov and his co-workers⁶¹⁸ were particularly active in using measured vicinal coupling constants together with modified Karplus relations to deduce conformations in peptides, while proton chemical shifts were also found useful for measuring *cis/trans* isomerization in proline peptides.^{619,620} A great deal of effort was put into the analysis of hydrogen bonding and solvent accessibility to peptide bonds as measured by the rate of H/D exchange of the peptide N–H protons, a method introduced in 1968 by Stern, Gibbons, and Craig.⁶²¹ In noninteracting solvents, linear oligopeptide chains as short as seven residues were found to adopt incipient α -helix conformations.^{618,622} NMR studies of both synthetic and naturally occurring cyclic peptides were particularly informative. In 1964, Schwyzer et al. studied the hexapeptide cyclo(GlyProGly)₂, which they found to be symmetric since only three sets of resonances were observed.⁶²³ Later, Blout and his colleagues⁶²⁴ investigated a series of synthetic peptides of the form cyclo(ProGly)_n for $n = 3, 4$, and 5, and determined the symmetry and conformation of the molecules in relatively noninteracting solvents, such as methylene chloride, and in water. Another example, shown in Figure 70 from work by Kopple et al.,⁶²⁵ illustrates the temperature-dependent studies used to elucidate internal hydrogen-bonding schemes. Likewise, natural cyclic peptides, such as the antibiotic gramicidin S and the hormone oxytocin, were studied by NMR to ascertain their conformational flexibility.^{626,627,628}

During this period, studies of proteins were generally limited either to certain resonances that fortuitously appeared outside the broad unresolved hump that corresponded to the bulk of the protein signals or to 'random coil' resonances that were

Figure 70 ^1H NMR (100MHz) of the amide region of a partially deuterated cyclic hexapeptide, cyclo(glycyl- d_2 -glycyl- d_2 -tyrosyl-triglycyl) in a DMSO-water solvent.⁶²⁵ (Reproduced by permission of the American Chemical Society)

revealed on disruption of the secondary and tertiary structure. Studies focused mainly on chemical shift measurements. Assignment and de novo structural conclusions for native systems were extremely difficult, and thus resolved resonances typically were used as empirical indicators of structural change to follow conformational transitions under widely varying conditions. In a series of papers during the early and mid-1960s discussed below, the existence of resolved resonances in native protein spectra was first revealed and the effects of denaturation on the spectra studied in detail.

In 1962, operating at 60 MHz, Arthur Kowalsky discovered two broad resonances at abnormally high field in the spectra of cytochrome *c* and myoglobin, ascribing them to side chains above and within the circumference of the aromatic porphyrin ring and thus subject to ring current effects.⁶²⁹ In a subsequent paper⁶³⁰ he extended these studies and reported the first observation of paramagnetic shifted resonances in ferricytochrome *c*, which appeared well outside the normal chemical shift range and disappeared in spectra of the diamagnetic form. These observations opened the door to a multitude of later publications, reflecting intense research efforts in many laboratories devoted to the study of paramagnetic proteins, including those rendered paramagnetic by the binding of 'unnatural' ions such as lanthanides. The availability of high-field superconducting magnets, discussed in the following section, contributed significantly to the advancement of these studies. Also, as described by Ivano Bertini (*Bertini, Ivano: A Life with Paramagnetic Molecules*), the very large shifts that were subsequently discovered, ranging, for example, between 200–300 ppm in high-spin cobalt(II) proteins, and excessive broadening of many of the shifted resonances, necessitated special techniques to increase the spectral width and handle dynamic range problems in both CW instruments and the later FT spectrometers.

International Conferences on Magnetic Resonance in Biological Systems

As magnetic resonance became a useful method for investigating a number of biological problems, the need for a forum to discuss these emerging techniques became apparent. Informal discussions among Mildred Cohn, Terry Eisinger, Oleg Jardetzky, Bill Phillips, and Bob Shulman soon led to the idea of an international meeting, and ultimately a series of such meetings —the International Conference on Magnetic Resonance in Biological Systems (ICMRBS). From the beginning, these conferences have been characterized by a spirit of enthusiasm and innovation, with an informal structure and a minimum of administrative overhead.

The first ICMRBS was held in Boston in 1964 and was followed by a second meeting two years later in Stockholm. These two meetings established the biennial series as truly international and set the stage for conferences that have largely alternated between western Europe and North America, with a few in more distant locations. The 30 meetings held through 1994 have been in Canada, England, France, Germany, India, Israel, Japan, the Netherlands, Sweden, Switzerland, and the United States.

This series of meetings covers biological applications in the whole range of magnetic resonance, not just NMR. In fact, the programs for the two earliest meetings were dominated by applications of electron spin resonance, which was then more readily applied to biopolymers and to living systems such as photosynthetic bacteria, than was NMR. Of the relatively few NMR talks, about half were devoted to metal-protein interactions. Over the years, as NMR has become more broadly applicable in biology, ESR remained a strong component in the program, but the balance has shifted to emphasize NMR applications to proteins, nucleic acids, and other biopolymers, to in vivo spectroscopy, and to imaging.

During the 1970s and into the 1980s, paramagnetic proteins provided a fertile field for systematic studies of magnetization transfer, relaxation rates, and steady-state and time-dependent NOEs, while the use of paramagnetic ions as probes of biomolecular structure and dynamics evolved into a broad field, utilizing ^{13}C , ^{14}N , ^{15}N , ^{31}P , and other nuclei for studies at nearly every level of biological complexity. In his historical sketch (*La Mar, Gerd N.: NMR of Paramagnetic Proteins*), Gerd LaMar describes the work of his group and others in using isotopic labeling to pin down assignments in heme proteins and thus take advantage of the information available from the large hyperfine shifts. Redfield and Gupta⁶³¹ used a saturation-transfer experiment to connect the resonances in oxidized and reduced cytochrome *c*, as Redfield describes in his historical sketch (*Redfield, Alfred G.: Foundations and Structures*):

This permitted an estimate of the electron-transfer rate, and shortly afterwards Gupta found our first NOE. These were the first observations of these effects by FT NMR and in a protein. In the spring of 1970, I reported our machine architecture and spectra at the Experimental NMR Conference, but I did not report the electron-exchange results that we obtained a week before since I assumed, erroneously, that others might

easily be able to do this experiment. However, I could barely contain myself from talking about them. These saturation-transfer results connected key assignments made separately by Wüthrich, Shulman, and Phillips in the two states of cytochrome c, thereby solidly confirming these results and showing that a methionine was coordinated to the heme in both states.

In 1965, Mandel⁶³² drew attention to the aromatic amino acid resonances (tyrosine, phenylalanine, tryptophan, and histidine) that appeared at the low end of the spectra of proteins, apart from the rest of the complex envelope of signals. Of particular interest was the imidazole C-2 proton resonance of histidine, which not only could be resolved from the rest of the aromatic protons, but whose chemical shift had been shown by earlier studies to vary with the pH of the solution.⁶³³ In Mandel's spectra, obtained at low and high pH, a peak corresponding to the C-2 proton resonances of all four histidine residues of ribonuclease was identified. Shortly thereafter, Bradbury and Scheraga⁶³⁴ managed to resolve three resonances ascribed to the four histidine residues of ribonuclease at intermediate pH values and plotted their change in chemical shift with the pD of the solution to estimate pK values. Subsequently, the histidine C-2 proton resonances of several proteins including ribonuclease were completely resolved in a classic paper by Meadows, Markley, Cohen, and Jardetzky,⁶³⁵ permitting studies of the effects due to pH changes and the presence of metal ions and inhibitors of enzymatic activity. Spectra from that paper and titration curves derived for each of the four histidine residues are shown in Figure 71. As Jack Cohen says in his historical sketch (*Cohen, Jack S.: Recollections of Early NMR Applications to Proteins and Cells*), these results confirmed the expectation of seeing one signal per histidine residue and demonstrated 'that the pK represented not an aggregate pK value, but rather reflects the local protein micro-environment'. He applied this concept to HEW and human lysozymes, where significantly different pK values for the single histidine resonance implied different local structures.⁶³⁶

One of the more interesting and far-reaching observations during this period was that certain resonances of small flexible molecules broadened on binding to biopolymers, while other resonances were relatively unchanged. The earliest studies, which appeared in the mid-1960s, involved the binding of small diamagnetic molecules such as coenzymes, substrates, and drugs to proteins. An example is found in a 1965 study that compared the relative relaxation rates of different peaks in the spectrum of penicillin G as a function of bovine serum albumin concentration, with the conclusion that penicillin binds through the interaction of the benzene ring with the protein rather than the penicillanic acid moiety.⁶³⁷ Ligand-binding studies were particularly attractive in a period when protein spectroscopy was difficult and relatively unrevealing, and are still in use today to provide quantitative information on binding constants that is unavailable by other techniques.⁶³⁸

The problem of poor resolution and overlapping lines in biopolymer spectra resulted in some creative solutions. For example, in 1965, Jardetzky proposed a form of spectral simplification in which selected protonated amino acid residues would be observed on the background of a nearly completely deuterated protein. Meanwhile, Katz and Crespi⁶³⁹ developed methods for preparing fully deuterated proteins from algae and, in 1968, obtained spectra of a protein that was fully deuterated except for the leucines.⁶⁴⁰ In 1970, Markley and

Figure 71 Top: 100 MHz proton NMR spectra of the aromatic region of RNAase A as a function of pH. Bottom: Titration curves of C-2 proton resonances of the histidine peaks shown in the spectra.⁶³⁵ (Reproduced by permission of the National Academy of Sciences, USA)

Jardetzky obtained greatly simplified spectra of the aromatic region of selectively deuterated analogs of staphylococcal nuclease, which were utilized for detailed NMR studies on enzyme-inhibitor interactions.⁶⁴¹ Isotopic substitution with deuterium was found to be advantageous also in diluting the proton spins, thus reducing the dipolar interaction that leads to line broadening and increasing the resolution in ¹H spectra. More recently, random deuteration has been shown to be an important adjunct to multidimensional NMR spectroscopy of proteins, again to reduce proton-dipolar interactions, as discussed in Section 14.

A reverse approach, in which deuterium is introduced at specific sites for assignment purposes, also became useful, particularly with high-field FT instruments where resolved resonances could be studied and/or high-quality difference spectra obtained.⁶⁴² In addition, deuterium substitution for the purpose of measuring ²H quadrupolar relaxation times also developed as an important tool during the 1970s for studying molecular dynamics in nucleotides and peptides, and the interaction of small molecules with proteins. This technique has been particularly important in studying oriented or partially oriented systems including model membranes and polycrystalline proteins, as discussed in Section 10.7.

The first spectra of random-coil DNA and synthetic polynucleotides were obtained in 1964.^{643–645} In these studies, all conducted at 60 MHz with preparations that were relatively polydisperse with respect to polymer molecular weight, no spectra were detected at ambient temperatures for double-stranded structures such as calf-thymus DNA and poly(A)-poly(U) mixtures. Above the melting temperature, however, the integrated intensity of broad peaks attributable to nonexchangeable base and ribose protons could be used to define a melting curve as the conformational integrity was disrupted. Similarly, in the earliest NMR observations of tRNA,^{644,646} several broad peaks corresponding to base and ribose protons appeared as the temperature was increased from 10°C to 90°C. Only spectral regions, rather than specific resonances, could be followed in these early studies, which were also complicated by concentration and salt conditions that contributed to the aggregation of tRNA.⁶⁴⁷

A Major Step Forward: The First High-Field Spectra

The introduction of the Varian HR-220 MHz spectrometer in 1964, operating with the first superconducting magnet, deserves a special place in this history. Although clearly there were limitations to the system as outlined below, the HR-220 made an enormous difference in the ability of many laboratories to make advances in biochemical research. Both sensitivity and resolution were substantially improved, and strongly coupled spin systems could be unraveled by the high field to produce spectra that could be readily analyzed by visual inspection or computer calculation and simulation. For example, it was clear from the earliest studies of nucleosides and nucleotides that ribose conformations could be estimated from application of a Karplus-type relationship to the magnitude of the vicinal couplings. However, those studies had to rely mainly on measurement of $J_{H-1'-H-2'}$ because of the complex spin systems. Complete analyses became possible at 220 MHz, as illustrated in Figure 72 by studies on the molecular conformation of uridine.⁶⁴⁸

At the high end of the molecular weight range, the improvements in the spectra of biopolymers were also very significant. Bob Shulman's historical sketch (*Shulman, Robert G.: My Years in NMR*) describes his experience at the 2nd International Conference on Magnetic Resonance in Biological Systems in Stockholm in 1966:

There I was electrified by the 220 MHz ^1H spectra of the small proteins RNase and lysozyme presented by Bill Phillips. Suddenly the spectra showed well resolved lines, particularly to higher and lower fields than the central resonances but even in the overlapping region between 1 and 7 ppm sharp resonances could be observed. My previous experience at 100 MHz had led to the conclusion, which was widely if not universally held, that there were very few sharp lines in macromolecules, so that the well resolved spectra at 220 MHz were very surprising. I returned to Bell Laboratories and within a week had ordered a 220 MHz spectrometer which, when it arrived in early 1967, was only the second such installation in the world.

In 1967 and 1969, Phillips and McDonald published the first 220 MHz proton spectra of native and denatured (random-coil) proteins and single-stranded DNA.^{649,650} They were able to resolve high-field shifted resonances in native lysozyme and cytochrome *c*, explore in more detail the spectral changes induced by denaturation, demonstrate that the spectrum of a

Figure 72 Proton NMR spectra of uridine at 60 MHz (bottom),¹⁷⁴ 100 MHz (middle),¹⁷⁴ and 220 MHz (top).⁶⁴⁸ (Reproduced by permission of Varian Associates and the National Research Council of Canada)

random-coil protein can be computed to close approximation using a set of characteristic random-coil amino acid chemical shifts, and estimate purine/pyrimidine ratios for DNA from different species. The work clearly had an impact. In their 1968 review entitled, 'High Resolution Nuclear Magnetic Resonance Studies of Biopolymers',⁶⁵¹ E. M. Bradbury and C. Crane-Robinson began:

An ex-postdoctoral student of a colleague recently wrote from the United States that everybody in the physical biochemistry field was making nuclear magnetic resonance (NMR) studies of biopolymers. This may be an exaggeration, but it is worthwhile to enquire why there should be this upsurge of interest in a technique which has been available to chemists for the past decade or more . . . The pioneers of these applications, Kowalsky, Cohn, and the Jardetzky's, have written extremely lucid and detailed introductions and reviews, while, more recently, details have appeared of the exciting work being carried out by Phillips, McDonald and co-workers at 220 MHz. It is the appearance of their work which has focused attention on the potential of magnetic resonance in the field of molecular biophysics.

High-field spectroscopy also opened a window of opportunity for studies of the hydrogen-bonded protons of polymers. In 1971, Kearns, Patel, and Shulman demonstrated that hydrogen-bonded imino protons in H_2O solutions could be observed in the 11–15 ppm spectral region.⁶⁵² The increased sensitivity and resolution of a 220 MHz spectrometer was essential in that study in order to overcome the extreme experimental difficulties of observing peaks corresponding to mM

concentrations in the presence of an enormous solvent water peak. The authors followed the broadening and subsequent disappearance of several semiresolved resonances as the temperature was increased. Further improvements in the resolution and sensitivity of later instruments contributed to extensive research efforts in a number of laboratories to identify the number of resonances contributed by secondary and tertiary structure base-pairs, the role of metal ions in stabilizing tertiary structure, the interaction of tRNA with intercalating drugs, and the kinetics of hydrogen-bond formation and disruption.

In 1967, Bob Shulman and his colleagues, including Kurt Wüthrich and Seji Ogawa, used their new 220 MHz spectrometer to embark on a study of hemoglobin. Shulman describes in his historical sketch (*Shulman, Robert G.: My Years in NMR*) the interpretation of the porphyrin resonances in hemoglobin, and later the preparation and NMR investigation of mixed valency hybrids from the α - and β -polypeptide chains to establish the process involved in the long-studied cooperative oxygen binding.

The Fourier Transform Era Begins

NMR spectrometers utilizing pulse FT methods became commercially available around 1970. The advantages of the pulse FT technique were rapidly exploited by biochemists, and opened a floodgate of applications that until then had been impossible due to the low sensitivity and inherent inflexibility of CW NMR spectroscopy. For example, one could now average in the time domain, typically resulting in as much as a 100-fold increase in sensitivity. This provided an enormous advantage in terms of sample size and length of the experiment. In the case of insensitive nuclei such as ^{15}N , it meant that natural abundance studies finally became feasible, and developments in ^{13}C NMR moved rapidly, as we note in the following section. Fourier transform also enabled the development of special editing and data processing techniques to simplify spectra, enhance resolution, and improve the signal-to-noise ratio. Also, for the first time, pulse sequences to measure relaxation parameters could be used with complex systems rather than single spectral lines.

Initially, the strong water solvent signal was an even greater problem with pulse FT methods than with continuous wave techniques, since its dominance in the FID created severe dynamic range problems. A number of methods were proposed to 'eliminate' the water peak and met with mixed success. Reducing the residual HDO peak in a D_2O solution to a manageable level could usually be achieved, but real mastery over the H_2O solvent peak did not come until much later.

Basically five different approaches were used, one of which—rapid-scan correlation NMR—simply avoided the problem by continuing to use CW rather than pulse methods, albeit with an efficiency comparable with pulse-FT techniques. Dadok and others using his 250 MHz spectrometer^{653,654} had considerable success with this approach, but it was not widely used elsewhere. The simplest technique, and one of the most commonly used, involved placing a simple selective presaturation pulse at the frequency of the solvent resonance. Taking up a suggestion advanced by Schaefer⁶⁵⁵ in 1972 in connection with ^{13}C studies, Campbell et al.⁶⁵⁶ were the first to apply the presaturation pulse to a sample of biochemical interest in 1974. They found that they could reduce the

intensity of a 90% H_2O solvent signal by a factor of almost 1000 without significantly affecting peaks more than 0.5 ppm away. The method was successfully employed in many subsequent studies, but at times presaturation complicated the study of exchangeable protons in H_2O because of saturation transfer effects.

In 1972, Patt and Sykes suggested an alternative approach, 'WEFT' (Water Eliminated FT),⁶⁵⁷ which employs a nonselective 180° , τ , 90° pulse sequence to null the water signal. Provided the compound of interest has a much shorter relaxation time than water (often the situation for larger biomolecules), data acquisition can be started at time τ and gives, in principle, an undiminished spectrum of the molecule of interest and no water signal. Benz, Feeney, and Roberts⁶⁵⁸ soon amplified on the conditions for the use of WEFT, and subsequently a number of modifications were suggested to optimize the method. WEFT was particularly successful in D_2O solutions, where it has been widely applied, but in H_2O a sufficient reduction of the water signal was much more of a challenge, requiring careful optimization of the conditions. Moreover, the technique could not be used if relaxation data were sought or for quantitative studies in certain situations.

Probably the most effective method, in general, is simply not to excite the solvent resonance initially. Redfield and Gupta pioneered the use of a long, selective pulse to observe the remainder of the spectrum without exciting the solvent resonance.²⁹⁵ Although a number of improvements were made, including Redfield's 2-1-4 pulse sequence introduced in 1975,²⁹⁶ and other similar composite pulses developed by many other investigators, the technique really became effective for dilute solutions in H_2O only during the late 1980s and early 1990s with improved instrumentation, including pulsed magnetic field gradients. The availability of pulsed field gradients also permitted van Zijl and Moonen⁶⁵⁹ to develop a novel approach to water suppression based on a modification of Stejskal and Tanner's technique for measuring diffusion coefficients. Because of the greatly different diffusion rates for water and biopolymers, this method permits excellent water suppression without interfering with the normal pulse excitation schemes.

Another area that benefitted enormously from FT techniques was ^{31}P NMR. In the early experiments by Cohn and Hughes, tricks such as using 12-mm thin-walled tubes (plastic containers of Hughes' Havana cigars) had permitted the observation of ATP spectra with good signal-to-noise ratios for concentrations down to about 0.1 M. Some 10 years later, increased field strength, sample spinning, and time-averaging techniques had improved the situation, but not enough for continuous wave ^{31}P NMR to be useful at mM concentrations. As David Gorenstein points out in his historical sketch (*Gorenstein, David G.: Developments in ^{31}P NMR*), the coupling of a new Nicolet 1080 FT data system with their Bruker HFX-90 pulsed spectrometer made all the difference in studies on the binding of mononucleotides to ribonuclease A. The ability to observe signals at mM concentrations transformed ^{31}P NMR into an extraordinarily useful tool for biochemical, biological, and medical applications. Notable milestones in the realm of biochemistry include the discovery that ^{31}P isotope shifts from the substitution of ^{16}O in phosphate groups by ^{18}O could be used to study enzyme mechanisms,⁶⁶⁰ and more recently the coupling of multinuclear MR and new synthetic techniques for the study of self-complementary

oligonucleotides to obtain information on the conformation and dynamics of the phosphodiester backbone.

Carbon-13 in Biochemistry

As we saw in Section 6, even before FT methods were developed, several laboratories were able to carry out studies of ^{13}C in natural abundance (albeit still at molar concentrations) by making use of the combined effect of better homogeneity, improved field stability, frequency-sweep instruments with broadband proton decoupling, and time-averaging techniques. The laboratories of J. D. Roberts and D. M. Grant, both intimately involved in the improvement of ^{13}C NMR techniques, were among the first to profit from the new-found capability by conducting extensive surveys of ^{13}C chemical shift data on steroids, sugars, nucleosides, nucleotides, and other natural products. Recalling this period in his historical sketch (*Roberts, John D.: A Personal NMR Odyssey*) Roberts notes, in particular, the work in his laboratory by H. J. Reich and M. Jautelat to assign the spectrum of cholesterol, D.E. Dorman's study of sugars, and J.G. Nourse's 'Herculean efforts with erythromycin antibiotics'. During the late 1960s and very early 1970s, the amount of ^{13}C data on biologically important substances accumulated in these and other laboratories was impressive, as demonstrated by the contemporary reviews by J. B. Stothers¹²¹ and George Gray.⁶⁶¹

During this same period, interest was kindled in the use of ^{13}C enrichment as a tracer technique for elucidating biosynthetic pathways, and also as a method for the assignment of ^{13}C resonances in complex biomolecules.⁶⁶² Beginning in 1966 with the work of Tanabe and Detre,⁶⁶³ there were several studies of natural products utilizing ^{13}C satellites in proton spectra, where an increase in the satellite intensity signaled the incorporation of a label at a particular site. In 1970, Tanabe and co-workers⁶⁶⁴ fed acetate labeled with ^{13}C at the carbonyl and methyl positions in two separate experiments to cultures of the fungus *Stemphylium radicinum*, and reported the first direct ^{13}C observations of biosynthetically labeled carbon atoms. Their approach not only identified the origin of the carbon skeleton, but allowed for an excellent proton-decoupled CW spectrum to be obtained at 25 MHz. Tanabe's work encouraged other investigators to use ^{13}C to probe metabolic pathways and study biosynthetic enzymes. The challenge for many during this period, however, was formidable: to obtain enough enriched material to give a sufficient signal-to-noise ratio in low-field spectrometers, even those using FT time averaging. Ian Scott's historical sketch (*Scott, A. Ian: 13C NMR Studies of Biosynthesis. A Quarter Century in Retrospect*) gives a good account of both the difficulties and the triumphs of the early experiments that used both enriched and natural abundance ^{13}C isotopes. Such studies became really practical only with the development of modern high-field spectrometers, with greatly improved electronics and probes, which have cut the amount of required material by some two orders of magnitude.

Biosynthetic random ^{13}C enrichment was utilized in the late 1960s simply as a means of increasing the sensitivity of the NMR experiment sufficiently to obtain chemical shift data. For example, in a series of papers using INDOR, CW, and then FT techniques, Hyman Sternlicht and co-workers used biosynthetic preparations of 15%-enriched amino

acids to measure chemical shifts, showing that resonances could be identified and assigned by the use of a set of empirical rules.^{665,666} As noted by Jim Feeney in his historical sketch (*Feeney, James: Personal Reminiscences on NMR*), isotopic labeling also permitted detailed investigations of protein–ligand complexes in which multiple conformational states could be characterized and the dynamics of the protein–ligand interaction studied. The use of isotopic labeling continued to be an important adjunct to NMR spectroscopy, both for increasing the intensity of specific resonances so that they could be identified and studied without interference from other signals, and for achieving sufficient sensitivity to study minute amounts (such as in vivo metabolites). Most recently, as discussed in Section 14, advances in genetic engineering have resulted in techniques to produce sizeable quantities of proteins labeled in ^2H , ^{13}C , and ^{15}N .

As a final footnote to the pre-FT era, we note the first natural abundance ^{13}C NMR spectrum of a protein (hen egg white lysozyme), published by Lauterbur in 1970.⁶⁶⁷ The 25 MHz spectrum was obtained by Roy Johnson in the Varian Applications Laboratory using a 25% aqueous solution of the protein in an 8-mm sample tube containing a 2-mm tube of ^{13}C -enriched CH_2I_2 for a field-frequency lock signal. After over three and a half days of signal averaging, a noisy but tantalizing spectrum was obtained. Lauterbur noted in this paper that only relatively small gains in sensitivity above that observed in this CW experiment were likely and that the future for the routine study of enzymes lay in pulse FT techniques.

^{13}C NMR spectroscopy was a particular beneficiary of pulse FT technology, and the new-found capability resulted in an explosion of applications to biochemical systems. With the introduction of FT techniques, the amount of sample required remained about the same, but after only about 10–12 h (an 'overnight scan') spectra could be obtained with peaks corresponding to as few as three carbons clearly observable. Allerhand, Cochran, and Doddrell⁶⁶⁸ were the first to obtain a ^{13}C FT spectrum of a protein, ribonuclease, and commented in their 1970 paper that

As expected, the ^{13}C spectrum was appreciably richer in detail than the corresponding proton spectrum. Natural abundance ^{13}C Fourier transform NMR appears to be a practical tool for the study of biopolymers in solution.

This new capability was truly noteworthy. In his 1973 review entitled 'Applications of ^{13}C Nuclear Magnetic Resonance in Biochemistry',⁶⁶¹ George Gray noted: 'What until recently was virtually unimaginable is now happening frequently, that is, the observation of ^{13}C NMR spectra of biopolymers such as large polypeptides or enzymes.'

Allerhand and co-workers were keenly interested in pushing the technique a step further to observe resonances corresponding to single carbon sites and thus improve the applicability of NMR for conformational studies. They decided to focus on nonprotonated carbons, showing that they are the least broadened by dipole–dipole interactions and appear in small numbers over a relatively wide chemical shift range. Their solution was to build a probe for 20-mm spinning sample tubes, significantly increasing the sensitivity of the experiment and the amount of sample required.⁶⁶⁹ As Eric Oldfield remarks in his historical sketch (*Oldfield, Eric: NMR Adventures in Chemistry and Biology*):

We used to cram 2–3 g of protein into the tube, and wait—but the spectra were extremely nice, although generally restricted

Figure 73 Partial 15 MHz ^{13}C spectrum of reduced cytochrome *c* obtained with a 20-mm diameter sample tube in 11.4 h.⁶⁶⁹ (Reproduced by permission of the New York Academy of Sciences)

to nonprotonated carbons. Of course, these days, such amounts of protein seem absurd—although with labeling the numbers of C-13 spins are about the same!

An example of the success achieved with this approach is given in Figure 73, where the γ -carbon resonance of a single tryptophan can be seen.

As recounted by David Doddrell in his sketch (*Doddrell, David M.: An Historical Perspective of Research Based Upon Misguided Advice*), the availability in 1971 of Allerhand and Clouse's ^{13}C FT spectrometer at the University of Indiana provided the impetus to measure and understand ^{13}C relaxation parameters:

Our fear was that they may be uselessly long (we guessed tens of seconds for protonated carbons) . . . Of course history proved that we were up to a factor of 100 too long in our guess; the major result of this work was that we had developed a simple method of studying solution molecular dynamics still in use today.

'The Domain of Solid State NMR'

While conventional high-resolution NMR was being employed extensively, other distinctly different approaches were also developed to study the structure and molecular dynamics of biochemical systems. These include the use of solvent water relaxation rates to probe biopolymers in solution (discussed earlier), and methods to study model membranes and solid compounds of biological interest.

During the 1960s, Chapman and co-workers had successfully used wide-line ^1H NMR to demonstrate the increase in mobility that occurs when phospholipids are heated above the gel-to-liquid crystal phase transition temperature.^{670,671} However, analysis of phospholipid bilayer model membranes was limited by their broad and featureless NMR spectra, a result of incompletely averaged anisotropic interactions. Consequently, techniques were developed to prepare small diameter vesicles by ultrasonic irradiation, yielding higher resolution ^1H , ^{31}P , and ^{13}C spectra that could be used for chemical shift and relaxation time measurements. For example, Metcalfe et al.⁶⁷² measured ^{13}C T_1 values in sonicated lecithin vesicles and related the data to the internal and overall mobility of the molecule.

Developments in the NMR study of liquid crystals also had an impact. In 1967, Lawson and Flautt²²⁵ extended this

work from classical thermotropic liquid crystals to a lyotropic mesophase, which can be considered as a model membrane system since it resembles qualitatively the phospholipids of biological membranes. The use of ^2H NMR in biomolecular structural studies was further catalyzed by the work of Charvolin et al.⁶⁷³ in 1973. They studied an oriented lamellar lyotropic liquid crystalline phase of perdeuterated potassium laurate and water, and observed seven distinct quadrupole split doublets when the angle between the normal to the lamellar plane and the applied magnetic field was 90° . This indicated different degrees of order for different C–D bonds, thus providing information on the relative mobilities of the various CD_2 and the terminal CD_3 groups.

Although the use of vesicles had provided a partial solution to the problem of resolution, the sonication technique itself created controversy over the extent to which it altered the physical and chemical properties of the bilayer model or natural membrane structure. In 1971, Metcalfe et al.⁶⁷² showed that ^{13}C spectra could be obtained from unsonicated dipalmitoyl lecithin and from erythrocyte membranes, but the lines were quite broad. A breakthrough came in the early 1970s, when it was found that quadrupole splittings from deuterium-labeled lipids could probe the ordering of unsonicated bilayer systems.^{674–676} These reports kindled increased interest in applications of ^2H NMR to biochemical problems, and from the perspective of the 1990s Ian Smith points out in his historical sketch (*Smith, Ian C. P.: Deuterium NMR: Reflections on its Evolution*) that 'the most dramatic contribution of ^2H NMR in biochemistry is undoubtedly in the field of biological membranes.' In 1976, Myer Bloom and associates⁶⁷⁷ introduced the quadrupolar echo method, thus solving one of the major experimental problems in ^2H spectroscopy at that time: signal loss due to instrumental dead-time in the very early portion of the FID. As pointed out by Bloom in his historical sketch (*Bloom, Myer: Personal Views of NMR History*), this new capability for producing distortion-free ^2H spectra, coupled with methods for analyzing the observed Pake doublet splittings, was a crucial step in the ability to study interactions between lipids and other membrane constituents such as proteins, peptides, or cholesterol. Also, by this time, Urbina and Waugh had published the first applications of ^{13}C cross polarization and high-power ^1H decoupling to unsonicated phospholipid bilayers, obtaining resolved resonances in both gel and liquid crystalline phases with linewidths determined only by chemical shift anisotropies,⁶⁷⁸ while Chapman and Oldfield collaborated with Doskočilová and Schneider to apply ^1H magic angle spinning to the study of membranes.⁶⁷⁹

All of these techniques, as well as methods for the analysis of ^{31}P and ^{13}C chemical shift anisotropy, were available in the mid-1970s. As summed up by J. Seelig in his historical sketch (*Seelig, Joachim: NMR and Membrane Structure*), 'by the end of 1976 the NMR toolbox for membrane studies was wide open and provided the instruments for many biophysical membrane studies to come.'

During the 1980s the combination of high-field spectrometers and magic angle sample spinning techniques finally yielded truly high-resolution ^1H spectra of lipids,⁶⁸⁰ opening a full range of opportunities for the study of natural membranes. NMR studies on the structural and motional properties of vesicles have also continued to this day, driven in part by

an increasing emphasis on potential medical applications such as drug delivery systems.

As a complement to the work on lipids, the 1970s and 1980s saw a growing number of applications of solid state techniques to both small biomolecules and biopolymers. This work was motivated both by the desire to capitalize on information from anisotropic interactions, such as dipolar couplings, and by the fact that standard NMR techniques are unusable when the isotropic reorientation of biomolecules becomes extremely restricted due to large molecular size or association into supramolecular structures such as membranes or virus particles. As Stan Opella remarks in his historical sketch (*Opella, Stanley J.: NMR Spectroscopy and Structural Biology*), 'This is the domain of solid state NMR spectroscopy, even if the samples are actually solutions'.

Two examples are illustrative of both the technical challenges associated with solid state NMR studies and the advances that have been made in the understanding of structure and internal motions of proteins in solid phases. Dennis Torchia describes in his historical sketch (*Torchia, Dennis A.: A Fortuitous Transformation*) his observation that polycrystalline amino acid and peptide model systems demonstrated a surprising amount of rapid molecular motion. This led to the development of equations for anisotropic spin-relaxation and powder lineshapes for a wide variety of models of molecular reorientation. The study of molecular dynamics in crystalline proteins came within reach, however, only when protein expression techniques could be employed to produce sufficient quantities of isotopically labeled protein to achieve the sensitivity and specificity needed for interpretable ^2H and $^{13}\text{C}/^{15}\text{N}$ solid state spectra. As Torchia says:

Initially we prepared polycrystalline protein samples containing one type of deuterated amino acid, and obtained clear evidence that the side chain of each type of labeled amino acid was mobile. In order to overcome the problem associated with overlapping powder patterns, we next obtained cross-polarized magic angle spinning spectra of $^{13}\text{C}/^{15}\text{N}$ labeled samples. These high-resolution spectra enabled us to observe signals corresponding to individual atomic sites in the protein.

Torchia found that the chemical shifts of the crystalline state almost universally matched those in solution, and thus embarked on heteronuclear NMR studies with his colleague Ad Bax at NIH to assign the solution spectrum (and thus the solid state spectrum) using heteronuclear NMR techniques.

In his historical sketch, Opella discusses the development of solid state spectroscopy to determine the structures of peptides and proteins using oriented samples. He provides an example of the application of these methods in studies of filamentous bacteriophage coat proteins:

Remarkably, these virus particles orient spontaneously with their filament axis aligned with the direction of the applied magnetic field. All of the structural studies of the filamentous viruses planned when the laboratory was being established at the University of Pennsylvania starting in 1976–79 were designed to take advantage of the fact that these nucleoprotein complexes could be oriented either as fibers, or later as solutions in the magnetic field of the spectrometer. By 1982–83, the implementation of selective ^{15}N labeling of both backbone and side-chain sites and magnetic orientation of virus solutions enabled the high-resolution structural information to be obtained on a protein in a supramolecular structure, the 10^7 dalton virus particles. Subsequently ^{13}C and ^{15}N NMR experiments were used to obtain data from a sufficient number of sites to yield a model of the fd coat protein in the bacteriophage.

In Section 8, we reviewed the development of multiple pulse and magic angle spinning methods that are designed largely to eliminate the line-broadening effects of dipolar interactions in solids. However, with the line narrowing comes the loss of information on interatomic distances that might be derived from dipolar coupling. In the 1980s, Bob Griffin and others, partly motivated by the desire to measure distances in solids of biological interest, developed methods to reintroduce the effect of homonuclear dipolar interactions in a controlled manner—high-resolution dipolar recoupling. The initial method, DIPSHIFT and its derivatives, were successful but were applicable only to molecules with strong dipolar coupling between directly bonded nuclei. What was needed were techniques applicable to weaker interactions from nonbonded ^{13}C , ^{14}N , and ^{31}P . As Griffin says in his historical sketch (*Griffin, Robert G.: Perspectives of Magnetic Resonance*):

At the time there was a double ^{13}C labeled glycine sample around the laboratory, left over from measurements of double quantum spectra in solids. Dan Raleigh performed a MAS experiment with this sample and happened to observe a pronounced broadening of the ^{13}C resonances at a spinning speed equal to one-third of the isotropic shift difference. We had rediscovered rotational resonance (R^2), a phenomenon initially reported by Raymond Andrew in 1963/65. We described the broadening in glycine in a short paper and pointed out that this was a recoupling effect which could provide internuclear distances. For long distances or weak couplings the lineshapes were too small to be useful, so I proposed a magnetization exchange experiment at R^2 for such cases.

Griffin and co-workers^{681,682} obtained the first distance measurements on a protein in 1989, and the method has subsequently been applied to other solids of biological importance.

Meanwhile, Jake Schaefer, who had pioneered the modern renaissance of MAS in ^{13}C studies, developed a related method for studying dipolar interactions between two different rare spins (e.g., ^{13}C and ^{15}N) and hence estimating their internuclear distance. This technique, REDOR (Rotational Echo DOuble Resonance),⁶⁸³ involves a cross-polarization/magic angle spinning experiment in which 180° pulses are added in careful synchronization with the rotor speed. A train of rotational echoes is thus created in which intensity alterations result from the dephasing of the magnetization of one spin in the presence of the local dipolar field of the other. By adjusting pulse timing and number of rotor cycles used, the results can be optimized for particular dipolar interactions in a sample containing chemically different carbons and nitrogens.

The Higher the Better: From 220 to 800 MHz ... and Up?

The Varian 220 MHz system in the 1960s and early 1970s had made an enormous difference in the ability of many laboratories to study complex biomolecules. However, there were some significant drawbacks, as described by Kurt Wüthrich (*Wüthrich, Kurt: NMR Structures of Biological Macromolecules*) and R. J. P. Williams (*Williams, R. J. P.: The Use of NMR in Biology: Personal Reflections*). The instrument was largely limited to CW field-sweep, proton-only, operation. The lack of a field-frequency lock and the need for high sample spinning rates led to instability problems during the long accumulations that are a requirement for most

biochemical studies. In addition, double resonance experiments were awkward, requiring homebuilt audiomodulation devices, and perhaps most importantly, data handling was limited to time-averaging computers (with very limited memory sizes) which could be interfaced to the system. In applications to biopolymers, the instrument did not provide sufficient resolution to be able to study the main envelope of signals in proteins. Disappointingly, says Williams, ‘... it proved impossible to get spectra better than those demonstrated by Jardetzky’s studies [at 100 MHz] started somewhat earlier. All that could be seen were some histidine residues.’

The next generation of spectrometers, operating at ^1H frequencies up to 360 MHz with pulse FT and multinuclear capability, was revolutionary in advancing the state of the art for NMR applications in biochemistry. In the early 1970s, as we saw in Section 6, a joint effort between Oxford University, Oxford Instruments, and Bruker had succeeded in producing the first 270 MHz FT spectrometer. Operating at a field three times that of the then standard Bruker spectrometer, the magnet had excellent resolution and stability and was immediately applied to studies of proteins. Williams describes the excitement of the 270 MHz instrument in his historical account:

We were able to carry out spin decoupling and NOE experiments for the first time in proteins. In fact it was clear to us all that protein structures could be studied and it became a matter of innovation in pulse sequences and in structure analysis in order for the objective to be reached ... We showed, more importantly, that the dynamics of proteins could be analyzed.

A Bruker 360 MHz instrument followed in 1976. For many investigators who had been largely restricted to 100 MHz instruments, the step from 100 MHz to 360 MHz was revolutionary, and there were major improvements in data-handling capability. Simply repeating some of the experiments from previous years provided a wealth of new results, and opportunities arose for doing experiments beyond measurement of chemical shifts, as we discuss in some detail in Section 14.

These instruments and their successors at 400, 500, 600, 750, and now 800 MHz, created a fertile ground for successful application of NMR to the most complex of biochemical and biological problems. Developments in pulsed NMR methodology were also, however, to become essential, as we shall see in the following section.

TWO-DIMENSIONAL NMR

The early years of the 1970s witnessed two discoveries in NMR that would have far-reaching consequences. Two-dimensional (2D) Fourier transform NMR was proposed in 1971, and a year or two later came the idea of using NMR to obtain macroscopic images. We shall discuss NMR imaging in detail in later sections. The reason for mentioning it here is that 2D NMR and NMR imaging crossed paths very early in their respective developments, as we shall see below. In this section we explore the origins of 2D methods, summarize the variety of techniques that have evolved, and indicate the range of applications that have been developed.

The Origins of 2D NMR

The concept of two-dimensional NMR was first articulated by the Belgian physicist Jean Jeener at an AMPERE Summer

School in 1971. The initial idea of 2D NMR grew out of Jeener’s studies of spin–lattice relaxation in liquid crystals. As he relates in his article (*Jeener, Jean: Reminiscences about the Early Days of 2D NMR*), Jeener tried to ‘cook up a pulse scheme’ to examine the relaxation matrix in a kind of stochastic mode. He was concerned about interference from coherent responses from multiple pulses and began investigating such phenomena. This work led to the proposal of a simple sequence of two 90° pulses separated by a time t_1 , which would be incremented between experiments just as in numerous other pulse sequences (e.g., that for measurement of T_1 by a ‘saturation-recovery’ method). The difference was that Jeener proposed to Fourier transform not only the FIDs following the second pulse but also to carry out a second Fourier transform with respect to the time variable t_1 . He showed that transfer of coherence as a result of the second 90° pulse would lead to cross peaks in a two-dimensional frequency plot. Jeener and Alewaeters tried to verify the theory experimentally but met with only partial success:

We tried to observe the effect experimentally on ethylbenzene, spending weekends working with the rather primitive FT spectrometer available in organic chemistry at our university. Due to bad phase stability of this spectrometer, and to our total lack of practice of high-resolution NMR, Gerrit Alewaeters could only observe some of the strongest cross peaks of the 2D spectrum with a signal-to-noise ratio just high enough to confirm that our quantum mechanical predictions were correct (not really a surprise ...), but too low to make the new technique look very usable. Formal publication was deferred until cleaner experimental confirmation would be available, but I kept spreading the idea by personal contacts, lectures (probably for the first time at the AMPERE Summer School in Basko Polje in 1971), and by circulating “unpublished” notes written in November 1971. [*Editor’s Note:* Jeener’s notes may now be considered ‘published’ since they were included as a scientific contribution in a book presented in 1994 to Anatole Abragam on the occasion of his 80th birthday.⁶⁸⁴]

Thomas W. Baumann, in Richard Ernst’s laboratory in Zürich, attended this Summer School and brought back detailed notes on Jeener’s talk, which he discussed with Ernst. In his article (*Ernst, Richard R.: The Success Story of Fourier Transformation in NMR*) Ernst says:

This was exactly the technique I had been waiting for. I had been thinking for some time about systematic computer-controlled double resonance experiments, but appreciated the complexity of the resulting 2D spectra should they follow the shape of the famous Anderson–Freeman plots. The Jeener two-pulse experiment appeared not to have this disadvantage.

Ernst (Figure 74) and his student Enrico Bartholdi carried out calculations to verify and probe the new idea, but Ernst initially planned no experiments because he considered 2D spectroscopy as ‘Jeener’s property’ and waited for his results to be published. Moreover, Ernst felt that his computer facility was inadequate for 2D data processing and storage. In 1973, Ernst corresponded with Jeener who showed him a rough draft of an unfinished paper (which was never published).

In April 1974, Ernst learned of Paul Lauterbur’s use of NMR to create two-dimensional images and realized that Jeener’s 2D technique could be adapted to this purpose. Ernst and his co-workers pursued this aspect, as we shall discuss in more detail in Section 13, and thus the first paper using 2D techniques by Kumar, Welte, and Ernst⁶⁸⁵ dealt with imaging, not spectroscopy.

Figure 74 Richard Ernst. (Courtesy of R. R. Ernst)

Meanwhile Ernst also undertook 2D spectroscopy experiments, partially in preparation for a talk at the VIth International Conference on Magnetic Resonance in Biological Systems, scheduled for Kandersteg, Switzerland in September 1974. Ernst carried out the initial experiment himself on a modified Varian DA-60 spectrometer and wrote the software for the associated Varian 620i computer with 16 K memory. He presented both the spectroscopy and imaging results and says:

It was little wonder that my rapidly concocted contribution was rated at the Kandersteg conference as premature! Sometimes, however, even prematurely born children survive and excel. . . . Modern times had started without being noticed at that instant.

The Foundations of 2D NMR Are Established

The first publication on 2D NMR spectroscopy was that of Müller, Kumar and Ernst,⁶⁸⁶ which appeared in December 1975. This communication described what would later be termed '2D *J*-resolved NMR', a method we discuss in Section 11.3. This work was soon followed by a long paper by Aue, Bartholdi, and Ernst⁶⁸⁷ which was the first formal exposition of the principles of 2D NMR. This publication presented a comprehensive view of the concepts of 2D NMR, together with detailed theoretical and experimental developments of virtually every imaginable aspect of the new technique. The authors dealt with the intensities, phases, and connectivities of transitions; they analyzed the unprecedented and complicated lineshapes that resulted from phase variation

Figure 75 Schematic representation of the four basic periods that characterize a 2D NMR experiment

in two dimensions; they examined the effects of relaxation and magnetic field inhomogeneity, and they considered consequences of strong coupling and limitations imposed by assuming only weak coupling. Moreover, this paper addressed the use of 2D pulse methods to excite and detect multiple quantum coherences.

The basic concept of 2D NMR is simple, and this seminal paper established the framework for treating the many hundreds of innovative variations that were to come. A 2D experiment makes use of four time periods (Figure 75) namely preparation, evolution, mixing, and detection. The preparation period is necessary to bring the system to a known state, often thermal equilibrium, and to place magnetization into the *xy* plane, frequently by application of a 90° pulse. During the evolution period (t_1), the spins are allowed to precess under the influence of the Hamiltonian provided by the molecular system, together with additional perturbations imposed by the experimenter. During this period each spin is, in effect, 'tagged' according to its frequency and at the end of the period has acquired a specific phase relation relative to the rotating frame. The mixing period determines, in large measure, just what the particular 2D experiment achieves. In some examples, this 'period' simply involves turning on or off some external perturbation (such as a decoupler), whereas in other cases a pulse or sequence of pulses may cause the wavefunctions of the spins to interact, or mix, in such a way that information from one is transferred to another. The free induction decay (FID) is then acquired, as in any FT NMR experiment, during the detection period (t_2). By incrementing the period t_1 , the phases of the spins at the beginning of the mixing period are systematically altered, with consequences that carry over into the acquisition period. Thus, each successive FID reflects the history of the spin system as a function of t_1 . The NMR signal $S(t_1, t_2)$ is thus a function of two time variables and can be double Fourier transformed with respect to both t_1 and t_2 , resulting in a two-dimensional frequency spectrum $S(F_1, F_2)$, which correlates the behavior of the spin system during the evolution period with that of the detection period.

Ernst and his group rapidly developed all of the ideas put forth in the 1976 paper, and many more. Ernst refers to 'playing with a new toy', as the ideas and experiments rolled out during the next two to three years. Initially, there was little competition. However, at Oxford University, Ray Freeman immediately appreciated the potential of the new method in providing a much more efficient way to gather large quantities of information that had been available only via the double resonance methods that he had, in part, developed. With only limited instrumentation (initially a Varian CFT-20, which could produce only 20 MHz ^{13}C FT spectra), Freeman and his group quickly conceived some important and novel 2D experiments, of necessity involving ^{13}C NMR. Also, at the University of California in Berkeley, Alex Pines, who was

largely interested in the NMR of solids, recognized the value of multiple quantum effects, thus beginning a line of research that would intersect the more advanced developments in 2D NMR. Meanwhile, at MIT, John Waugh initiated a different set of experiments in which 2D methods were applied to studies of solids.

The power of 2D NMR in studies of liquids, as illustrated by papers coming primarily from the Ernst and Freeman groups in the latter half of the 1970s, inspired an increasing number of NMR spectroscopists to turn to these methods and persuaded NMR instrument companies to develop the necessary hardware and software. High-field spectrometers (up to 400 MHz) were available with generally good sensitivity, and computers had advanced during the last decade to accommodate one-dimensional FT experiments in a reasonably efficient manner. The additional requirements to perform 2D experiments involved mainly software changes, which in the early days were made by individual workers themselves depending upon the experiment desired. Toward the end of the 1970s suitable programs became available along with more versatile pulse programming and phase control. Appropriate software changes for special experiments could be made as and when required. In order to store the large data array $S(t_1, t_2)$ in a 2D experiment, disk storage units became a part of NMR spectrometers but were very limited by later standards.

Plotting the vast amount of data from a 2D experiment was not a trivial problem. Initially, results were presented as a 'stacked plot' of a series of conventional spectra drawn behind each other, as illustrated in Figure 76. 'Whitewash' routines in computer programs were devised to raise the recorder pen whenever a given trace was about to overwrite a peak in the previous trace. The stacked plot is esthetically appealing, but is often difficult to analyze. An alternative display mode, the contour plot (Figure 76), gradually gained favor, even though many old-time spectroscopists had difficulty visualizing the results without the familiar spectral curves.

As in the early days of 1D Fourier transform NMR, improvements in computer capability provided a major impetus. The greatly increased demands for data storage and rapid processing of 2D data could not be met for several years, and it was not until the 1980s that the 2D revolution really began on a broad scale. When it did, however, growth was exponential. Literally hundreds of different experiments or modifications and improvements of previous methods were developed. Almost every one was distinguished by a catchy name or acronym, resulting in a bewildering array of techniques. To provide a flavor of the rich variety of 2D methods, we discuss the development of some of the principal techniques, but with the recognition that many more types of experiments are not included here.

2D *J*-Resolved NMR

The initial experiment proposed by Jeener involved a pair of 90° pulses and would serve as the foundation of a large series of experiments to be discussed in the following sections. However, much of the early exploitation of 2D NMR capabilities centered on the manipulation of the spin system Hamiltonian by controlling some external perturbation, such as spin decoupling. This freedom to change the experimental conditions is responsible for numerous applications of 2D

Figure 76 Typical presentation of data from 2D NMR experiments. Top: Stacked plot. Bottom: Contour plot

NMR. If two different NMR parameters operate in the two time intervals t_1 and t_2 , these parameters are separated in the two frequency domains F_1 and F_2 after the Fourier transformation. Examples are the separations of multiplet structure from chemical shifts in liquid state NMR and the separation of dipolar couplings from chemical shifts in solid state experiments (which we discuss later). The 2D methodology permits a correlation to be established between the spin systems as they exist in the two states.

One example of such experiments is 2D *J*-resolved NMR, which was first reported by Müller, Kumar, and Ernst.⁶⁸⁶ The experiment consisted of allowing ^{13}C magnetization to precess without decoupling during t_1 , then observing the signal during t_2 while broadband decoupling is applied. The

Figure 77 2D J -resolved ^{13}C spectrum of n -hexane. The ω_1 axis shows the coupled ^{13}C -H multiplets, while the ω_2 axis displays the proton-decoupled ^{13}C spectrum.⁶⁸⁶ (Reproduced by Permission of the American Institute of Physics)

Figure 78 Top: Conventional 200 MHz ^1H spectrum of the molecule shown. Bottom: The equivalent of a broadband homonuclear decoupled spectrum from the 45° projection of the 2D J spectrum, with pseudo-echoes used in the t_2 domain to suppress dispersion mode contributions. Peaks marked 'SC' are artifacts from the strong coupling.⁶⁹⁷ (Reproduced by permission of Academic Press)

spectrum of n -hexane shown in Figure 77 clearly demonstrated the power of the method in correlating the coupled and decoupled ^{13}C resonances and showed the potential of 2D methods for facilitating spectral assignments. Freeman and co-workers⁶⁸⁸⁻⁶⁹¹ quickly developed improved versions of this method, as did the Ernst group.⁶⁹² They provide advantages of additional spectral simplification, resolution, data presentations, or experimental convenience, along with the separation of various multiplets by means of the selective excitation of individual carbon species. Most of the versions utilize homo- or heteronuclear spin echo formation during the evolution period, with or without heteronuclear decoupling, in order to simplify the motion of the system during the evolution period by the elimination of selected terms of the Hamiltonian. In 1982, Bax and Freeman⁶⁹³ suggested a useful variant of

the 2D J -resolved experiment which involved the proton flip using a selective 180° pulse. It inverts certain ^{13}C satellites in the proton spectrum in order to measure ^{13}C - ^1H long-range couplings.

Although complete *homonuclear* decoupling could be of considerable practical importance as an aid in the analysis of complicated spectra, particularly of large molecules, it is difficult to achieve in the liquid state. Aue, Karhan, and Ernst⁶⁹⁴ described an indirect technique to achieve the equivalent of a homonuclear broadband decoupled ^1H spectrum. They applied a spin echo sequence during t_1 and started data acquisition at the peak of the echo to generate a 2D J -resolved ^1H spectrum, and showed that the projection of the 2D data set onto the F_2 axis produced the equivalent of a homonuclear decoupled spectrum. Bax et al.⁶⁹⁵ introduced an alternative approach using a 'constant time' method in which the total evolution period remains constant as t_1 is incremented. This method permitted the measurement of the absorption mode rather than the less resolved absolute value, but improvements were also forthcoming for absolute value presentation. Nagayama et al.⁶⁹⁶ manipulated the data by 'tilting' the axes and Bax, Freeman, and Morris showed how resolution could be improved by suppressing the dispersion mode contribution.⁶⁹⁷ An example of this procedure is shown in Figure 78.

Homonuclear Chemical Shift Correlation via Scalar Coupling

Jeener's initial description of 2D NMR focused on an experiment in which two 90° pulses are used to transfer coherence between two nuclei that interact by scalar coupling. Ernst and his co-workers realized that this concept could be used to establish coupling relationships that often are

diagnostic for the elucidation of molecular structure. Spin decoupling had long been the principal method for obtaining such information, but here was an alternative that could provide data for *all* coupling networks simultaneously, not one at a time as in a typical decoupling experiment. Thus the multiplex advantage that characterized FT NMR and so improved the efficiency of data acquisition had an analog in the initial 2D work.

Techniques for establishing such spin connectivities rapidly became the most popular 2D experiments in both homonuclear and heteronuclear modifications. The correlation between nuclei with different chemical shifts can be displayed as off-diagonal signals, or 'cross peaks' in a two-dimensional plot with the F_1 and F_2 axes representing the frequencies observed after Fourier transforming the two time domains. The homonuclear version of Jeener's original experiment was dubbed COSY (for *COR*related *S*pectroscopY), while the heteronuclear version has had several acronyms. Although the pulse sequence in the COSY experiment is quite simple, the underlying concepts are complex and required a rigorous theoretical development by Ernst and co-workers, employing a density matrix treatment and later the development of the product operator formalism.⁶⁹⁸

In its initial form, COSY had a number of drawbacks, particularly with the limited phase-shifting ability of the spectrometers at the time, coupled with restricted computer capabilities. An early variant of COSY, *Spin Echo Correlated Spectroscopy* (SECSY), proposed by Nagayama, Wüthrich, and Ernst,⁶⁹⁹ proved useful in these early days, but as computers and instruments improved, the reduced spectral dispersion and asymmetric data presentation required by SECSY became overriding disadvantages, and the method was largely displaced by COSY and other, newer techniques. One key advance was the development of phase-sensitive COSY methods by States, Haberkorn, and Ruben⁷⁰⁰ and by Marion and Wüthrich,⁷⁰¹ a technique that proved valuable in overcoming limitations in spectral resolution and sensitivity.

Many other improvements in the basic COSY method have been suggested and implemented. For example, DELAYED COSY, a normal COSY sequence modified by inclusion of a fixed delay (Δ) after the evolution period and prior to the acquisition time, was described by Bax and Freeman⁷⁰² and applied with considerable success for the derivation of long-range coupling information. Kumar et al.⁷⁰³ proposed SUPER COSY in which the antiphase character of the cross peaks is transferred to the diagonal peaks, while Cavanagh and Keeler⁷⁰⁴ showed that the diagonal peaks in COSY spectra can be suppressed by a difference technique.

Substantial improvements in lineshapes and in the suppression of unwanted peaks have been achieved through various 'filtering' procedures. For example, Oschkinat et al.⁷⁰⁵ introduced z -COSY, a technique in which in-phase coherence is converted at one point to z magnetization, while antiphase components can be eliminated by phase cycling, unfortunately with loss in overall sensitivity. Other modifications of COSY use multiple quantum filters as proposed by Piantini, Sørensen, and Ernst,⁷⁰⁶ in which undesired components are converted to unobservable multiple quantum coherences while the desired information is recovered from observable magnetization. (A more detailed discussion of the origin and application of multiple quantum effects in general is presented in Section 11.7.)

Double quantum filtered (DQF) COSY is the variant which is most widely employed since it uses only 90° phase shifts, whereas higher quantum filtering requires other than 90° phase shift capabilities. In DQF-COSY, the normal COSY pulse sequence is followed by a minimal duration fixed delay and then a third 90° pulse, whose phase is cycled independently of that of the second. DQF-COSY experiments have been used extensively to simplify 2D spectra. If a system, for example, has a large number of methyl or methoxy groups (which in general provide minimal connectivity information), the methyl/methoxy proton signals dominate and present dynamic range problems in the normal COSY spectra. In the DQF version, such resonances are substantially reduced in intensity. Another important application of multiple quantum filtering is to remove strong signals of solvents such as water, which is most frequently employed in biological systems.

A technique called *Exclusive CORrelation Spectroscopy* (ECOSY), where the coherence transfer takes place exclusively between connected transitions as long as the spins are weakly coupled, was proposed and utilized by Griesinger, Sørensen, and Ernst.^{707,708} It is based on the fact that the coherence transfers between connected transitions and between nonconnected transitions have different dependences on the rotation angle β of the mixing pulse. A simple alternative to ECOSY called PECOSY (*Primitive ECOSY*) has been proposed by Müller.⁷⁰⁹ Like ECOSY, the technique provides simplified cross-peak patterns by restricting coherence transfer to connected transitions, but it is simple in that it is a regular COSY with the mixing pulse restricted to small flip angle β . Several other 2D experiments involving the properties of multiple quantum coherences such as Bilinear COSY and UNCOSY have been proposed and used by Levitt et al.⁷¹⁰ and by Farmer and Brown,⁷¹¹ respectively.

COSY experiments normally provide information only on the connectivity between vicinal or geminal protons, which have significant spin coupling constants. Often, however, it is important to establish longer-range connectivities by relaying magnetization beyond a pair of directly connected spins. The idea of relayed coherence transfer was put forth by Eich, Bodenhausen, and Ernst⁷¹² in 1982. In relayed correlation spectroscopy, usually called RELAY, the second pulse of the COSY sequence is replaced by a 90° , τ , 180° , τ , 90° sequence which induces two consecutive coherent transfer processes. Results for crotonaldehyde, an AMXQ₃ coupling network, are shown in Figure 79. The aldehyde proton A shows resolvable coupling to M but is not significantly coupled to Q or X. The RELAY spectrum at the bottom provides an unambiguous proof that all the six spins belong to a single coupling network, while the normal COSY spectrum does not reveal connectivities between A and either Q or X (empty circles in the top portion of the figure). More sophisticated sequences can be designed to relay the information over a greater number of couplings, but the use of RELAY is limited by small couplings because of relaxation during the relatively long coherence transfer period.

A technique in which cross peaks are generated between all members of a coupled spin network, leading to the most complete correlation diagram, was developed by Braunschweiler and Ernst⁷¹³ and named *Total Correlation Spectroscopy* (TOCSY). It uses a mixing period during which a rapid series of 180° pulses is applied in order to suppress Zeeman

Figure 79 RELAY spectrum of crotonaldehyde (bottom) showing both short-range and long-range couplings. COSY spectrum (top) with the signals from long-range couplings missing.⁷¹² (Reproduced by permission of the American Chemical Society)

Figure 80 Comparison between a COSY spectrum (top) and a TOCSY spectrum (bottom), showing additional long-range couplings identified by TOCSY.⁷¹³ (Reproduced by permission of Academic Press)

interactions and chemical shifts, while retaining all spin couplings. During this 'isotropic mixing' period, coherence can be exchanged among the spins without regard to the magnitude of individual coupling constants. Figure 80 gives an example of a TOCSY spectrum and a comparison with a conventional COSY spectrum. In its initial form, TOCSY was difficult to apply to complex systems because of several experimental problems, but later improvements made the technique very useful.

Meanwhile, Bax and Davis⁷¹⁴ developed a related method of isotropic mixing based on their analysis of cross polarization originally found in solids by Hartmann and Hahn. In his historical sketch (*Bax, Ad: NMR of Ethanol and Interferon-γ*), Ad Bax describes the origin of this work as he and Don Davis looked for the source of artifacts in another experiment:

It was my solid state NMR experience that tipped us off to the real cause of these anomalous cross peaks: they were due to

homonuclear Hartmann–Hahn cross polarization. . . . Once we had recognized the origin of the Hartmann–Hahn artifacts, it was relatively straightforward to capitalize on them and use them for obtaining J connectivity. For maximum Hartmann–Hahn transfer, the goal was to make the trajectories of coupled spins as identical as possible. In retrospect therefore not surprising, our improved Hartmann–Hahn cross polarization schemes started to look more and more like heteronuclear decoupling schemes, where the objective is to make ^1H spins coupled to ^{13}C in the $-\alpha$ and $-\beta$ spin states undergo identical trajectories.

With suitable spin-locking, such a *HO*monuclear *HART*mann–*HA*hn (HOHAHA) experiment can provide efficient coherence transfer through a large spin system. Just as in the TOCSY experiment, the duration of the mixing period controls the extent of propagation. Initially Bax and Davis proposed the use of Malcolm Levitt's MLEV-16 sequence,²⁴⁹ consisting of 16 composite 180° pulses, but subsequently an uncompensated 180° pulse was added to make it MLEV-17 in order to overcome phasing problems. With this improvement, the HOHAHA/TOCSY method has proved to be a durable and widely applicable technique.

Heteronuclear Correlated Spectroscopy

Correlations between ^1H chemical shifts and those of other nuclei, particularly ^{13}C , play an important role in assigning spectra and in elucidating structures in complex molecules. Several 2D techniques have been developed to facilitate this process, again largely supplanting the multiplicity of decoupling or other double resonance experiments that might otherwise be required. These methods provide for the separate or simultaneous evolution of spins of the two species, coherence transfer in one or more steps, and observation of one of the two species. The early 2D experiments generally relied on observation of the less abundant nucleus (e.g., ^{13}C) because such studies could be more readily implemented with the instruments of the 1970s and early 1980s. However, the potential advantages of inverse detection of ^1H were recognized and later used extensively, as we discuss in Section 11.8.

2D heteronuclear correlation of ^{13}C and ^1H chemical shifts was proposed almost simultaneously by the Ernst and Freeman groups,^{715,716} and one of the first demonstrations of its value in chemistry was given by Bodenhausen and Freeman.⁷¹⁷ These experiments involve the application of an initial 90° pulse to protons, an evolution period t_1 to allow free precession of the protons, a second 90° ^1H pulse to create nonequilibrium spin populations, and a 90° ^{13}C pulse to effect coherence transfer to ^{13}C , the free induction decay of which is detected. An example of the use of this technique is given in Figure 81, where the 2D spectrum of camphor emphasizes the correlation of the low-field ^1H chemical shift with the high-field ^{13}C shift.

As 2D methods were implemented in commercial spectrometers, these correlation techniques became a staple under such names as HETCOR, Hetero-COSY, and Chemical Shift Correlation Map. Heteronuclear shift correlation experiments have been employed for assignment purposes for protons and ^{13}C and protons and ^{15}N for directly bonded nuclei. Correlations of other nuclei, such as protons and deuterium in small molecules, boron–proton, fluorine–proton, and phosphorus–proton, have all been obtained. Extension to long-range coupled nuclei has

Figure 81 2D $^1\text{H}/^{13}\text{C}$ spectrum of the methyl-groups in camphor, showing chemical shift correlations for the *gem*-dimethyl groups, b and c. Arrows denote weak responses transmitted through long-range couplings.⁷¹⁷ (Reproduced by permission of the American Chemical Society)

also been feasible by appropriate selection of the delays during the pulse sequences, or by developing other pulse sequences in order to improve the sensitivity. Kessler et al.⁷¹⁸ introduced and used the sequence COLOC (*CO*relation spectroscopy via *LO*ng range *C*oupling), while Freeman and co-workers^{693,719} employed different approaches for the same purpose.

Several modifications of the correlation experiments have also been proposed. In most of the heteronuclear shift correlation experiments, the H–H spin multiplets in the F_1 dimension are retained. Although coupling information is often extremely useful, the splittings can result in sensitivity loss or spectral overlap problems. Bax⁷²⁰ and Garbow et al.⁷²¹ independently developed techniques to collapse such multiplets, thus achieving the elusive goal of broadband decoupling of protons attached to ^{12}C from those attached to ^{13}C . This procedure, *BI*linear *RO*tation *DE*coupling (BIRD), has become widely used in other connections as well.

Heteronuclear relayed coherence transfer techniques were developed by Bolton⁷²² and Bax.⁷²³ They employ the same pulse sequence as the homonuclear case except for additional 180° and 90° observe pulses. In the heteronuclear RELAY experiment, information is passed from remote protons to protons bonded directly to ^{13}C and finally to the ^{13}C itself. Information on ^1H – ^1H couplings is thus transferred to the observed nucleus. A single carbon in the relayed heteronuclear correlation experiment could have more than one peak arising from the directly bonded protons and the protons two bonds away, but the 1J coupling can be removed through ‘low-pass J filtering’ described by Kogler et al.⁷²⁴

2D Exchange Spectroscopy

The impetus for Jeener’s concept of 2D NMR came from his interest in relaxation processes. At the Gordon Conference on Magnetic Resonance in 1978, Jeener suggested to Ernst a pulse sequence that could provide relaxation data, as Jeener

Figure 82 Chemical exchange in the heptamethylbenzonium ion, as measured by 2D NMR.⁷²⁶ (Reproduced by permission of the American Chemical Society)

put it, 'easily ... much simpler than my original dreams.' This sequence uses three pulses: 90° , t_1 , 90° , τ_m , 90° , t_2 . If two nuclei, tagged by their precession frequencies during t_1 , exchange magnetization during the mixing period τ_m , either by magnetic dipolar relaxation or by chemical exchange, cross peaks will occur in the 2D spectrum.⁷²⁵ Jeener did not have the instrumentation to develop this technique and readily agreed to a collaboration with Ernst's group. They found it difficult initially to detect cross relaxation effects in the small molecules with which they were working, but they were readily able to observe cross peaks from the chemical exchange of methyl groups in the heptamethylbenzonium ion,⁷²⁶ as shown in Figure 82. The peaks for the four nonequivalent methyl groups (1,1'; 2,2'; 3,3'; and 4) appear along the main diagonal with the intensity ratio 2 : 2 : 2 : 1, while the off-diagonal peaks immediately establish the exchange network $1 \rightleftharpoons 2 \rightleftharpoons 3 \rightleftharpoons 4$.

The detailed theory underlying 2D studies of cross relaxation and of transient NOEs, a technique called *Nuclear Overhauser Effect Spectroscopy* (NOESY), was developed by Macura and Ernst.⁷²⁷ The first use of the 2D technique for measurements of intramolecular NOEs was demonstrated by Kumar et al.⁷²⁸ who obtained data on a small globular protein, basic pancreatic trypsin inhibitor (BPTI). NOESY rapidly became an invaluable tool in biomolecular structure, as discussed in Section 14.

With nuclei of high isotopic abundance, both cross relaxation and exchange usually produce indistinguishable 2D data, but a variation of the experimental parameters, such as temperature or mixing time, can sometimes differentiate between the two phenomena. Alternatively, a method proposed initially by Bothner-By et al.⁷²⁹ for the measurement

of NOEs in the rotating frame under spin-locked conditions distinguishes clearly between NOE and exchange. The experiment was initially named CAMELSPIN (Cross relaxation Appropriate for Minimolecules Emulated by Locked SPINs), but quickly became better known as ROESY⁷³⁰ (Rotating frame Overhauser Effect Spectroscopy) by analogy to NOESY. The value of the NOE in the rotating frame increases monotonically with increasing value of τ_c , the molecular correlation time, so ROESY is particularly valuable in obtaining NOE information for molecules with correlation times of the order of $1/\omega$, where the magnitude of the ordinary laboratory frame NOE goes through zero.

Rotating-frame experiments produce simultaneously coherence transfer through scalar coupling and cross relaxation, which may lead to undesired interference and ambiguities between TOCSY and ROESY effects. Griesinger et al.⁷³¹ introduced a technique which provides clean TOCSY spectra and suppresses contributions from cross relaxation based on opposite signs of the longitudinal and transverse cross relaxation rates, while Bax and Davis showed how ROESY effects could be measured without interference from effects transmitted via spin coupling.⁷³⁰

Multiple Quantum Coherences

The basic theory of NMR, built on first-order time-dependent perturbations, shows that allowed transitions are limited to those in which quantum number m_I changes only by ± 1 . Values for Δm other than unity (including $\Delta m = 0$), which are called 'multiple quantum transitions', were observed in atomic and molecular beams by various workers in the 1950s, and Hughes and Geiger⁷³² predicted in 1955 that the energy level schemes usually encountered in NMR experiments are particularly suitable for the observation of these nominally forbidden multiple quantum transitions. They were first observed in 1956 by Wes Anderson,⁷³³ who was studying relaxation in 2-bromo-5-thiophene. As he increased the rf power to induce saturation in individual lines, he observed the effects shown in Figure 83. Spectrum (c) showed a line at the center of the spectrum that occurred only at large rf fields, which Anderson attributed to double quantum transitions. He also observed multiple quantum transitions in *p*-chlorobenzoyl chloride. Meanwhile, Kaplan and Meiboom⁷³⁴ found and explained similar transitions in ethyl alcohol and 1,1,2-trichloroethane, and Yatsiv⁷³⁵ provided a further theoretical treatment. In 1963, Anderson, Freeman, and Reilly⁷³⁶ used double quantum transitions as aids for assignments of NMR spectral lines.

After these initial observations, there was little additional research in multiple quantum NMR. With the advent of FT NMR methods, the prospects for studying multiple quantum transitions (MQT) appeared bleak because the FID is recorded in the absence of rf radiation; hence it is not possible to detect such transitions directly. However, with the advent of 2D NMR, Aue, Bartholdi, and Ernst⁶⁸⁷ showed that not only double quantum transitions but also zero quantum transitions (preferably termed *coherences*, rather than transitions) could be detected indirectly. They developed the basic theory, suggested several experimental approaches, and demonstrated the effects, as shown in Figure 84. In general, the experimental procedure involves the generation of

Figure 83 ^1H NMR spectrum (30 MHz) of 2-bromo-5-chlorothiophene.⁷³³ (a) Low rf power; (b) rf power increased by a factor of 3.4; (c) rf increased further by a factor of 3.4. Note the double-quantum transition in (c). (Reproduced by permission of the American Physical Society)

multiple quantum coherence through some excitation process, its evolution during t_1 , and conversion to observable single quantum coherence during the mixing period.

Wokaun and Ernst⁷³⁷ followed up this work by discussing methods to detect MQTs and by pointing out three areas in which MQTs could be valuable. (a) They can be utilized for the assignment of spectral lines in complex spectra. Since the number of transitions decreases as Δm increases, the higher quantum spectra are normally easy to interpret. (b) Zero quantum transitions are insensitive to magnetic field inhomogeneities and thus permit the recording of high-resolution spectra in inhomogeneous magnetic fields. (c) They permit the determination of relaxation parameters in a simple manner with high accuracy. The Ernst group continued to

Figure 84 ^1H NMR spectrum (60 MHz) of 2,3-dibromothiophene, obtained with a pulse sequence $90^\circ, \Delta, 90^\circ, t_1, 90^\circ, t_2$, with $\Delta = 236$ ms. The multiple quantum coherence generated by the first two pulses results in lines in the ω_1 dimension from zero quantum (z) and double quantum (d) transitions, as well as the two doublets of the normal single quantum spectrum.⁶⁸⁷ (Reproduced by permission of the American Institute of Physics)

improve methods for studying MQTs and to explore various applications.^{738,739,740}

Meanwhile, Alex Pines and co-workers, in their study of solids, were led to multiple quantum effects, as Pines describes in his historical sketch (*Pines, Alexander: Solid State NMR: Some Personal Recollections*):

Our original intention was to study hydrogen NMR in solids, to provide an alternative to homonuclear multiple pulse sequences, this time by diluting protonated samples with deuterium. The idea was reminiscent of the approach taken earlier with carbon, and here again there was a heteronuclear interaction that needed to be decoupled. The hydrogen–deuterium coupling, however, seemed futile to average because the wide, quadrupole broadened deuterium line would require prohibitive radiofrequency power, but it was conceivable that we could exploit double quantum decoupling which had recently been used by Meiboom and co-workers in liquid crystals. Indeed, narrowband irradiation of the $(+1, -1)$ transition of the deuterium with modest power yielded a resolved hydrogen spectrum, and in this way we could observe the chemical shift anisotropy of hydrogen in ice—a notoriously difficult system for homonuclear multiple-pulse techniques. . . . The next question, which emerged from our double quantum decoupling work and our previous experience with indirect detection of invisible microwave coherences, involved the possibility of preparing and observing, in the time domain, the ‘forbidden’ deuterium double-quantum transition.

The Pines group pursued this objective, and beginning in 1976 they published several papers that described the theory and experimental implementation of double quantum deuterium NMR.^{741–744} Concurrently, Hashi et al.^{745,746} were pursuing similar types of research.

Shimon Vega, who made major contributions in his work with Pines, describes in his historical sketch (*Veeman, Wiebren S.: Personal Reflections on Solid State NMR in the Early Days*) his previous introduction of a set of fictitious spin- $\frac{1}{2}$ operators to simplify the density matrix description of zero-field NQR of spin-1 nuclei. Such operators played an important role in the detailed theory of double quantum NMR published by Vega and Pines.⁷⁴² Pines et al. developed a number of additional aspects of multiple quantum effects, including the n -quantum phase shift, bilinear rotation decoupling (BIRD),

Figure 85 Multiple quantum ^1H NMR spectra of benzene oriented in a liquid crystal solvent. Top: Complete multiple quantum spectra. Bottom: Selective excitation of only $n = 0, 4$.⁷⁴⁷ (Reproduced by permission of the American Institute of Physics)

multiple quantum filtering, and selective excitation of n -quantum spectra. Many of the techniques developed initially for solids were found to be applicable to liquids as well. Selective excitation is illustrated in Figure 85, where n -quantum echo spectra and selective excitation of only zero- and four-quantum spectra are shown for benzene oriented in a liquid crystal.⁷⁴⁷

One of the best known and potentially most useful of the many experiments that capitalize on multiple quantum effects is INADEQUATE, a method which suppresses resonances from isolated ^{13}C nuclei while retaining signals from molecules with coupled ^{13}C – ^{13}C pairs, as mentioned in Section 7.6. Developed initially by Bax et al.,^{748,749} it was modified into a 2D version as well.⁷⁵⁰ The pulse sequence (90° , t , 180° , t , 90° , 90°) generates double quantum coherence and reconverts it to observable single quantum magnetization. The

signal-to-noise ratio is often a problem with INADEQUATE because it depends on only 0.01% of the molecules, and several improvements have been proposed, including the use of quadrature detection of t_1 ^{751,752} and the application of composite pulses.⁷⁵³

Proton-Detected Heteronuclear Shift Correlation

Double resonance methods, especially INDOR, had long been used to observe a more sensitive nucleus in order to obtain information about a less sensitive nucleus to which it is spin coupled. With the advent of 2D NMR it became possible to carry out similar studies, but with the advantage of covering a broad spectral range in a single experiment. The initial 2D heteronuclear chemical shift correlation experiments

Figure 86 Pulse sequence for indirect detection of S magnetization by observation of I . The initial I pulses saturate the normal I magnetization and provide a nuclear Overhauser enhancement of S .⁷⁵⁴ (Reproduced by permission of Elsevier Science)

were proposed by Maudsley and Ernst⁷⁵⁴ in 1977. Their pulse sequence (Figure 86) is a generalized version of the homonuclear COSY sequence. Magnetization of S , the less sensitive nucleus, evolves during t_1 and is transferred to I , which is detected, thus providing the correlation between the spins but with the sensitivity of I , in contrast to the other heteronuclear correlation techniques discussed in Section 11.5. If S represents a spin such as ^{13}C at low natural abundance, this apparently simple method encounters difficulty in discriminating against artifacts from the large fraction of I not coupled to S . More sophisticated techniques, together with an improvement in instrumentation, would be needed before indirect detection methods became commonplace.

A distinct advance was made by Bodenhausen and Ruben⁷⁵⁵ who used the pulse sequence of the INEPT experiment (Section 7) first to transfer proton magnetization to ^{15}N and, after it had evolved during the period t_1 , to transfer it back to ^1H , which is detected. The method worked for natural abundance ^{15}N as well as for enriched samples, but a measurement was very time consuming even for concentrated solutions. In addition, the complex pulse scheme did not readily lend itself to solvent suppression. Nevertheless, this procedure, originally termed the ‘Overbodenhausen experiment’ but later called heteronuclear single quantum correlation (HSQC), has subsequently been modified and incorporated into many more complex pulse sequences, as discussed in Section 16.

In 1979, Luciano Müller⁷⁵⁶ introduced a pulse technique, superficially similar to the INEPT sequence but with different phase relationships, that creates heteronuclear zero and double-quantum coherence between the I and S spins, then, after evolution, transfers these coherences to I magnetization which is observed. The method was demonstrated only for an enriched ^{13}C sample and did not attract much attention.

A dramatic improvement in the sensitivity of the indirect measurement of ^{15}N NMR was demonstrated by Bax, Griffey, and Hawkins⁷⁵⁷ in 1983, when they formulated a new pulse sequence (called *Heteronuclear Multiple Quantum Correlation*, HMQC) that carries out a transfer process similar to Müller’s method but with improved efficiency. The experiment can be carried out with only a single ^1H 90° pulse, adjusted to have a null in its excitation profile at the solvent water frequency and thus providing good suppression of the solvent signal. Their application of the method to ^{15}N samples at natural abundance and to a 0.7 mM solution of enriched tRNA provided a clear demonstration of the utility of this

approach. As Bax says in his historical sketch (*Bax, Ad: NMR of Ethanol and Interferon- γ*): ‘Although the same HMQC pulse schemes, together with a large number of alternative schemes, were proposed independently by the Australian group of Doddrell, Pegg, and Bendall,⁷⁵⁸ the application of our experiment to a biological macromolecule and to natural abundance peptides was probably the main reason for the surge in popularity of these HMQC experiments.’

Other improvements in the sensitivity of indirect detection have been advanced. For example, Palmer et al.⁷⁵⁹ showed that as much as a factor of $\sqrt{2}$ in sensitivity can be gained by refocusing and detecting two orthogonal in-phase proton magnetization components, rather than the conventional single component. In recent years, indirect detection methods have steadily become more popular and easier to implement with commercial spectrometers.

Use of 2D NMR in Structure Elucidation

The structure elucidation of organic molecules continues to be the most widespread application of NMR spectroscopy. Initially, the analysis of NMR spectra relied almost exclusively on correlations of chemical shifts, general ranges of coupling constants, and a great deal of chemical knowledge. In Section 5 we gave one example of this process at work in the structure elucidation of an alkaloid. The availability of double resonance methods, particularly selective spin decoupling to elucidate spin coupling patterns and the nuclear Overhauser effect to estimate spatial proximities (in favorable cases) provided powerful tools to assist in interpretation. But double resonance experiments are tedious and cannot always be readily applied to large or complex molecules.

The development of a very wide variety of 2D methods, some of which we have only touched on briefly here, made a dramatic change to the way in which chemists could approach the problem of structure elucidation. Many 2D techniques can now be applied in an automated manner with commercial software, and their sensitivity is such that it is often almost as easy and as fast to carry out a 2D experiment as to obtain a simple one-dimensional spectrum. In fact, a carefully chosen series of 2D experiments can often provide an unambiguous molecular structure of even a very large organic molecule.

One example, among very many that could be cited, is the elucidation of the structure of desertomycin, an antibiotic of molecular weight 1192,⁷⁶⁰ the first molecule of such size to be successfully handled solely by 2D NMR methods augmented only with knowledge of the molecular weight and a general elemental analysis. DQF phase-sensitive COSY and HOHAHA established much of the proton–proton coupling network, while the general carbon framework was deduced from ^1H – ^{13}C correlation experiments, especially *Heteronuclear Multiple Bond Correlation* (HMBC) which provides correlations through more than one C–C bond. Without software to aid in the analysis, the process of integrating the vast amount of NMR data to produce the structure shown in Figure 87 was labor intensive but logically straightforward.

Higher Dimensional NMR

The various two-dimensional NMR techniques discussed in this section and the developments of required instrumentation

Figure 87 Structure of the antibiotic desertomycin, as deduced from 2D NMR studies.⁷⁶⁰ (Courtesy of A. Bax)

have revolutionized the capabilities of NMR for dealing with complex molecules. The information which is restricted to one frequency in a one-dimensional experiment is spread out over the entire (F_1 , F_2) plane, a process that results in the enhancement of the resolution and a simplification of the spectral analyses. It was recognized very early in the development of 2D NMR that the general 2D experiment can theoretically be extended to three or more dimensions, which should add further capabilities. However, there were practical difficulties arising from the immense size of the required multidimensional data matrix $S(t_1, t_2, t_3)$ and problems in devising useful experiments that give good sensitivity and are artifact free. Such methods could be exploited only after improvements in instrumental and computer facilities and additional experience in optimizing the component 2D pulse sequences. Meanwhile, some experiments intermediate between 2D and 3D spectra were developed.

Two-dimensional exchange spectroscopy contains a third time variable, the mixing time τ_m , which is normally maintained at a fixed value for a particular 2D study. However, to map out dynamic processes it is often essential to vary τ_m systematically, in addition to t_1 and t_2 . To avoid the time needed to obtain a 2D spectrum for each value of τ_m , Bodenhausen and Ernst^{761,762} proposed a novel experiment in which t_1 and τ_m are incremented synchronously: $\tau_m = kt_1$. This 'Accordion' experiment increases the information content of the 2D spectra by incorporating exchange-type information into the 2D peak shape and produces spectra which effectively represent projected 3D spectra.

The next stage of development of 3D NMR spectroscopy was the experiment by Bolton,⁷⁶³ who obtained ^{13}C spectra in which the signals were modulated by both chemical shift and spin-spin couplings, but it would be about five years before true 3D experiments came into use.

In 1987, Vuister and Boelens⁷⁶⁴ reported a homonuclear three-dimensional J -resolved experiment in which the intensities and the phases of the cross peaks of a COSY experiment

were modulated by J couplings, permitting the determination of spin multiplets. They applied the method to a single-stranded DNA octamer. During the same year, Griesinger et al.⁷⁶⁵ implemented high-resolution correlation spectroscopy in three frequency dimensions. They described a practical approach to 3D NMR, suggested a technique for reduction of data matrices, and mentioned applications where 3D spectra could provide information that would be difficult or impossible to obtain from a series of 2D experiments. Their general formulation of a 3D experiment in terms of two 2D pulse sequences and naming based on the 2D components has been widely used. Initially used combinations, such as COSY-COSY, COSY-NOESY, and NOESY-COSY, have largely given way to NOESY-NOESY, TOCSY-NOESY, or HOHAHA-NOESY as the generally most useful homonuclear 3D methods. In a 3D experiment, the free induction decay is recorded as a function of two independently incremented time periods t_1 and t_2 , which leads to a quite large 3D data matrix. Griesinger et al. proposed the use of selective pulses to restrict the 3D volume and thus reduce the number of data points without sacrificing resolution. The results of a soft COSY-COSY experiment applied to a three-spin system (2,3-dibromopropionic acid) are shown in Figure 88, which illustrates various methods of data presentation.

Freeman and co-workers^{766,767,768} proposed a distinctly different approach to 3D correlation spectroscopy as a direct extension of pseudo-correlation spectroscopy (ψ -COSY), where a frequency-selective pulse is stepped through the F_1 dimension, perturbing one NMR transition at a time. The ψ -COSY 3D experiment does not involve excessively large data matrices or long three-dimensional Fourier transformations. At nearly the same time, Redfield and co-workers⁷⁶⁹ used a 2D multiple quantum coherence experiment to separate signals of a protein in two dimensions, then irradiated selectively to obtain NOE information. They referred to the method as 'saturation transfer 2D forbidden echo'.

Perhaps the greatest need for three- and four-dimensional NMR has been found in studies of proteins, where severe overlap is found in a multitude of resonances. We defer further discussion of multidimensional NMR experiments to Section 14.

Selection of Coherences by Pulsed Field Gradients

Most 2D experiments are subject to artifacts resulting from pulse imperfections and other nonideal factors. A major consideration in the design of any successful 2D technique is a procedure to eliminate or minimize such artifacts, usually by phase cycling. With more sophisticated experiments, especially 3D and 4D techniques, the requirement for sometimes extensive phase cycling on top of a long series of repetitions to cover the evolution time(s) can lead to excessively long experimental times. In many instances, the use of pulsed magnetic field gradients can reduce or eliminate the need for phase cycling.

The dephasing of magnetization in the presence of a magnetic field gradient and its rephasing when the gradient is reversed was first noted by Herman Carr in his 1952 Ph.D. thesis,⁶⁵ as mentioned in Section 4. It was clearly recognized in the early 2D work on multiple quantum effects that an n -quantum coherence evolves at n times the rate of a single

Figure 88 3D ^1H NMR study of 2,3-dibromopropionic acid. Top: One-dimensional spectrum. Bottom: Three 2D planes selected, as indicated, from the full 3D data set.⁷⁶⁵ (Reproduced by permission of Academic Press)

quantum coherence (magnetization), and Wokaun and Ernst⁷³⁷ pointed out the effects of magnetic field gradients in dephasing or rephasing such coherences. By manipulating the direction, magnitude, and length of application of gradients, it is feasible to eliminate certain coherence orders while retaining others. Papers by Bax et al.,⁷⁷⁰ Barker and Freeman,⁷⁷¹ and the Ernst group⁷⁷² showed the potential value of using pulsed field gradients, but practical application was limited because the time needed to stabilize B_0 inside the probe after such a strong gradient pulse was very long.

In the late 1980s, with a strong impetus from NMR imaging (as we shall see in Section 13), methods were developed for shielding the probe body and B_0 from the effects of the gradient pulse. The adaptation of self-shielded gradient coils to high-resolution NMR, described in Ralph Hurd's historical sketch (*Hurd, Ralph E.: A Brief History of Gradients in NMR*), led to increasingly widespread use of 'gradient enhanced' 2D and 3D pulse methods. For example, John et al.⁷⁷³ showed that the efficiency of a 3D ^{15}N HMQC-TOCSY study in proteins could be significantly

improved by application of magnetic field gradients, and the Kaptein group⁷⁷⁴ exploited the technique for more rapid data acquisition in triple resonance experiments. However, many gradient methods for selecting a particular coherence pathway reject not only unwanted pathways but the 'mirror image' of the desired pathway, thus exacting a price by reducing sensitivity. Bax and Pochapsky⁷⁷⁵ showed that gradient pulses can be applied so as to destroy only unwanted magnetization (for example, while the desired magnetization is temporarily aligned along the z axis) without any loss in sensitivity, and demonstrated that protein spectra of uncompromised quality could be recorded in less than two hours.

Suppression of the solvent water resonance has long been critical to the observation of NMR in samples of biological interest, as discussed in some detail in Section 10. Generally, those methods that are most effective in suppressing water also provide nonuniform excitation across the rest of the spectrum. With the use of pulsed field gradients, alternative—and very effective—methods have become available. For example, van Zijl and Moonen⁶⁵⁹ showed that the large difference in diffusion coefficients between water and biopolymers can be exploited to reduce the water signal by a factor of about 10^4 to 10^5 . The WATERGATE method, introduced by Piotto, Saudek, and Sklenar,⁷⁷⁶ excites all resonances equally but includes a 180° refocusing pulse which has a narrow gap in its excitation profile at the H_2O frequency. Pulsed field gradients select only magnetization that experiences the refocusing pulse, thus dephasing and virtually eliminating the water signal. This procedure lends itself to incorporation into complex multidimensional pulse sequences without any significant increase in the overall experiment time.

2D Experiments in Solids

With the wide range of pulse methods and magic angle spinning techniques developed in the late 1960s to obtain high-resolution spectra of solids, as discussed in Section 8, solid state NMR provided fertile ground for the new concepts of 2D NMR in the early 1970s. The initial work by John Waugh and co-workers^{777,778} was aimed at measuring dipolar interactions and chemical shifts for ^{13}C in single crystals separately, but in a way that they could be correlated. The pulse sequence for the *Separated Local Field* (SLF) experiment, illustrated in Figure 89, served as the prototype of a large number of 2D techniques that would be developed for solids. For example, Linder, Höhener, and Ernst⁷⁷⁹ applied the SLF method, combined with off-resonance magic angle proton decoupling during t_1 , in order to separate dipolar effects from chemical shielding anisotropy. Meanwhile, Griffin and co-workers developed the SLF method further by adding slow magic angle spinning, along with a WAHUA pulse sequence during the evolution period.⁷⁸⁰ By carefully synchronizing the pulses with the rotational period, they were able to observe rotational echoes and obtain rotational sideband spectra that provided information on both the principal values and the relative orientations of the shielding and dipolar tensors. These techniques were employed to obtain structural data such as ^{13}C – 1H and ^{15}N – 1H distances in powder samples. Later, the Griffin group modified the method to improve its efficiency and reduce signal loss by relaxation during the experiment.⁷⁸¹

Gary Maciel and co-workers introduced two very useful 2D experiments in the early 1980s. Szeverenyi et al.⁷⁸² employed

Figure 89 Pulse sequence for the Separated Local Field (SLF) method. After cross polarization, spin S (^{13}C) precesses under the influence of dipolar interactions during t_1 , but is decoupled from I (1H) during t_2 .⁷⁷⁸ (Reproduced by permission of the American Institute of Physics)

a combination of 2D NMR with CP MAS to study chemical exchange and spin diffusion. The pulse sequence is the same as the NOESY sequence originally proposed by Jeener et al.,⁷²⁵ except that the initial 90° pulse applied to the carbon spins for liquids is replaced by a cross polarization sequence. Subsequently, a large number of investigators studied both exchange and spin diffusion in solids with this method and modifications introduced later. Spiess and co-workers⁷⁸³ extended the method to deuterium, where exchange can be measured cleanly in the virtual absence of spin diffusion, and applied the technique as described in Spiess's historical sketch (*Spiess, Hans Wolfgang: Multidimensional Solid State NMR of Polymers*). Another interesting adaptation of the basic spin exchange technique was made by Grant and co-workers when they correlated the chemical shifts of ^{13}C lines in a single crystal at two different orientations by flipping the crystal from one orientation to the other during the mixing period.⁷⁸⁴

In 1983, Bax et al.⁷⁸⁵ introduced a new 2D technique for providing the isotropic chemical shift of a powder in one dimension and the static chemical shift anisotropy pattern along the other frequency axis. The experiment is performed using discrete 'hops' between evolution segments rather than continuous sample spinning. No spinning sidebands are observed. The experiments showed promise for obtaining powder patterns for individual peaks of complex molecules for which a straightforward nonspinning approach would yield only broad bands of overlapping powder patterns. Subsequently, the Griffin group demonstrated improved performance with an alternative technique, in which slow spinning during t_1 generates data on chemical shielding anisotropy while high-speed spinning during t_2 provides narrow lines.⁷⁸⁶ The magnetization is stored along the z axis while the spinning speed is changed. Tycko et al.⁷⁸⁷ achieved the same type of presentation by applying 180° pulses synchronized with the sample rotation. Later, Gan⁷⁸⁸ developed a slow MAS method in which magnetization evolves during three segments of each rotor period spaced at 120° . Again, the magnetization is stored along the z axis between segments.

A double CP MAS experiment, proposed by Schaefer et al.,^{789,790} uses successive cross polarization transfers to permit the selective observation of one type of rare spin which is

directly bonded to another. The cross polarization from ^1H to ^{13}C and then from ^{13}C to ^{15}N , for example, with final ^{15}N detection provides a ^{15}N spectrum containing resonances only from the ^{15}N nuclei which are directly bonded to ^{13}C .

THE EVOLUTION OF IN VIVO NMR

NMR began in physics laboratories. However, it was not long before a curiosity developed to stick something that was alive in the spectrometer and see what happened. Thus the co-discoverers of NMR actually conducted the first known in vivo NMR experiments, as described by Raymond Andrew in Volume 3 of this Encyclopedia *Magnetic Resonance Imaging: A Historical Overview*:

Soon after the first successful NMR experiments at Stanford University, Bloch obtained a strong proton NMR signal when he inserted his finger in the radiofrequency coil of his spectrometer. In 1948, Purcell and Ramsey in turn inserted their heads into the 2 T field of the Harvard University cyclotron; around their heads was a coil connected to a powerful radiofrequency generator tuned to the proton NMR frequency. The only sensation recorded was that of the EMFs generated in the metal fillings of their teeth as their heads were moved into and out of the magnet and detected by their tongues.

Interest in living systems, however, very quickly went beyond curiosity. As NMR gained importance in biochemical investigations, there were many efforts to apply NMR as a noninvasive tool in biology. Most early attempts were limited by the geometry of the NMR magnets and probes of the time, usually with an NMR sample tube that was typically 5–15 mm in diameter. The same technical problems that limited biochemical applications at the time—sensitivity, resolution, dominance of the water signal in proton spectra, and the relative inflexibility of continuous wave NMR instrumentation—made biological applications difficult. During the 1970s, first the availability of pulse FT techniques and then the introduction of high-field superconducting magnet systems with multinuclear capability resulted in an upsurge of interest as physiological concentrations in the millimolar range became readily observable. By the early 1980s, wide-bore horizontal magnet systems that could accommodate large animals and humans, innovative probe designs such as surface coils, and localization techniques had become available, thus creating a revolution for in vivo NMR research.

This section traces the development of in vivo NMR spectroscopy as it evolved from experiments on isolated cells and excised organs or tissue to studies of intact animals and humans. (We have adopted a broad interpretation of the term in vivo in this article to include preparations of cells, subcellular organelles, and excised organs and tissues, along with intact microorganisms, animals, plants, and humans.) As we shall see, results from in vivo NMR studies provided the impetus for the development of NMR imaging, a subject that forms the basis for Section 13.

Water and Ions in Cells and Excised Tissues

The first efforts to use NMR to step into the realm of living systems focused on the signals observed from abundant small molecules such as water and electrolytes. Shaw and Elsken

of the US Department of Agriculture placed 3-mm diameter cylinders of plant tissue (apple, potato, and maple wood) in a radiofrequency coil at 15 MHz to measure the water content in native and dehydrated states.⁵⁹² This work, published in 1950, was followed by several additional NMR studies by Shaw and co-workers of water in hygroscopic biological materials.

In 1955, Odeblad and Lindström published the first NMR measurements obtained on living cells and excised animal tissue. In their words, 'In biologic samples, rather complicated phenomena due to the viscosity, presence of paramagnetic enzymes, water adsorption on proteins, etc., predominate. It therefore seemed to be of interest to obtain information concerning certain characteristics of the proton magnetic resonance in biologic objects.'⁷⁹¹ The experiments, conducted at 26.5 MHz, were limited by the inhomogeneity of the magnetic field (typical linewidths were 10 ppm). The area of the water signal was measured by using a planimeter on photographs from the output of the oscilloscope screen, and relaxation times were obtained by a saturation recovery method where the growth of the signal height was recorded on moving film. Although the authors collected data on a broad array of biological samples—rabbit liver, striated muscle, fat tissue, calf cartilage, human Achilles tendon, human blood cells, and living yeast cells—not much could be concluded. The following year, they extended their studies on human red blood cells, using a 16 MHz 'high-resolution' spectrometer with spinning sample tubes and a resolution of less than 1 ppm. They could distinguish narrow and broad spectral components that differed in their exchange rates with D_2O .⁷⁹²

Odeblad and co-workers went on in succeeding years to publish the first NMR observations on a number of other biological preparations, including cervical mucus, human milk, tissues and fluids of the eye, vaginal cells, human saliva, and uterine muscle. In 1961, Odeblad published a paper entitled 'A Department for Medical Research with Nuclear Magnetic Resonance',⁷⁹³ and in 1968 he used T_1 measurements on human cervical mucus to detect ovulation.⁷⁹⁴

In 1964, Bratton, Hopkins, and Weinberg⁷⁹⁵ measured relaxation times of water in a living frog skeletal muscle and found that T_2 increased when the muscle contracted isometrically, whereas T_1 was not affected. They speculated on possible restricted rotational freedom of intracellular water and its variation as the muscle contracts.

Meanwhile, other investigators were also thinking about the state of water in biological tissue and began to use NMR as a probe of the mobility of water and ions. During the 1960s and 1970s a very large amount of work was published on relaxation, diffusion, and chemical exchange of water in cells and tissues of all sorts. For the most part, the NMR methods used were standard techniques of the sort we have discussed previously. The unique features were the attempts to interpret this body of NMR data, together with other information, in terms of models of the behavior of water in complex, ordered, anisotropic environments. A very good review by Raj Mathur-de Vr ⁷⁹⁶ summarizes the work done in a number of major laboratories and gives several general conclusions:

A considerable effort has been devoted to investigate the relaxation times of water nuclei (^1H , ^2H , ^{17}O) for a variety of biological samples as a function of temperature and frequency. One common and striking feature observed in nearly all cases studied is that the relaxation times of water nuclei and the diffusion constants of water molecules are much lower than the values observed for free water. Generally, these results can be interpreted in terms of: (1) the restricted and anisotropic

motion of water molecules and enhanced proton transfer in the hydration layer; and (2) the preferential and dynamic orientations of water molecules in the vicinity of biological macromolecules. ... Two-state and three-state models were proposed to account for the relaxation behaviour of water nuclei. ... There is conclusive evidence showing that water does not serve as an inert medium, but it participates at the molecular level in basic biological interactions and in fundamental biological processes.

Although considerable effort was expended in trying to use NMR data to support a model of the cell put forth by Gilbert Ling,⁷⁹⁷ the results, analyses, and interpretations from NMR, while providing valuable parameters, were never able to provide conclusive evidence for or against any particular theory of cellular function.

Sodium-23 NMR was also exploited in studies of cells, largely because of its relatively high NMR sensitivity and cellular concentration. The early observations of ²³Na by Jardetzky and Wertz in 1956 had included studies of several physiological samples including whole dog blood, plasma, red blood cell and ghost suspensions in saline, and hemolysate. However, Freeman Cope was the first to investigate ²³Na by continuous wave NMR in tissues from muscle, kidney, and brain.^{798,799} He found, as did others, that only about 40% of the known sodium could be accounted for by the integrated NMR intensity, and concluded that the remainder of the ²³Na signal was 'invisible' because the sodium ions were so immobilized that their resonance is greatly broadened. He interpreted these results in terms of Ling's model for the structure and operation of the cell. However, in erythrocytes, which also constitute a living cellular system, virtually all the sodium could be observed.⁸⁰⁰ In 1972, Shporer and Civan⁸⁰¹ showed that the ²³Na NMR signal in a liquid crystal was split into one sharp resonance and two very broad resonances with relative intensities 40 : 30 : 30, as expected for quadrupolar relaxation of the spin- $\frac{3}{2}$ ²³Na in an anisotropic environment. Soon, Berendsen and Edzes⁸⁰² showed that in tissues such as muscle, electric field gradients from a partial ordering of macromolecules over distances of the order of 100 Å could explain the results without requiring that 60% of the sodium ions are immobilized. The ²³Na studies were further complicated by the fact that intracellular and interstitial ²³Na generally have the same chemical shift. Only in the 1980s could the two components be cleanly separated by a shift reagent, Dy(P₃O₁₀)₂³⁻ introduced by Gupta and Gupta,⁸⁰³ and a more stable dysprosium complex later proposed by Springer and co-workers.⁸⁰⁴

In 1971, Raymond Damadian made an important discovery that would have long-term consequences. With the background of observations of cellular water, Damadian anticipated possible differences in NMR relaxation times for water in normal cells and cancer cells. He measured T_1 and T_2 in pieces of tissue excised from normal rats and from fast-growing tumors that had been implanted into other rats,⁸⁰⁵ and found that each of the eight tumor samples had longer relaxation times than any of the normal samples. These results raised questions in two areas: whether NMR could provide fundamental information about cancer and whether relaxation times in excised tissue could be used as an adjunct to the pathologist's microscopic examination to diagnose malignancy. Hollis, Saryan, and Morris⁸⁰⁶ soon repeated the measurements with other types of tumors. While they

confirmed Damadian's results of long T_1 values with fast-growing tumors, they found some ambiguities with slow-growing tumors. Interestingly, from the NMR standpoint, both Damadian (from Downstate Medical Center in New York) and the Hollis group (from Johns Hopkins University) made their NMR measurements at NMR Specialties, a small company near Pittsburgh, PA, where at that time one of the few reliable pulse instruments was available for making relaxation measurements.

The initial encouraging results gave rise to a number of further studies of excised tissues, primarily from patients where conventional diagnosis by pathology examination was done independently and often in a 'double-blind' experiment. The generally accepted conclusion from the whole body of work was that relaxation times in excised tissues showed such wide variability that relaxation measurements could not be used as a definitive method to distinguish among tissues that are normal, malignant, or pathological but not malignant.⁸⁰⁷ Nevertheless, the attention of a large number of NMR investigators had been drawn to the possibility of using this method in medical diagnosis. As we shall see in Section 13, this was one of the factors that eventually led to the development of NMR imaging as a medical diagnostic tool.

High-Resolution Studies

In the early 1970s, with the advent of pulse Fourier transform (FT) techniques and high-field spectrometers of ever increasing sensitivity and resolution, applications of NMR to living systems began in earnest. During the first half of that decade, a number of landmark papers appeared clearly demonstrating the potential of ¹³C, ³¹P, ¹H and other nuclei as probes for biological processes in vivo.

The first high-resolution spectra obtained on a preparation of isolated living cells were published in 1972 by Nick Matwiyoff and co-workers at the Los Alamos National Laboratory. After first using ¹³C NMR at 25 MHz to examine whole-blood samples treated with ¹³CO, ¹³CO₂, and ¹³CN⁻,⁸⁰⁸ they obtained spectra of whole cells of the yeast *Candida utilis* which had been randomly enriched to a ¹³C level of 20% and suspended in D₂O.⁸⁰⁹ A number of broad peaks were observed in the yeast suspensions that could be associated with particular types of carbon atoms by comparison with spectra of cell fractions and published spectra of known cellular constituents. The authors demonstrated that the metabolism of a specifically labeled substrate [¹⁻¹³C]glucose could be observed directly in living yeast cells, and commented:

This successful demonstration of the use of ¹³C as a label both for cellular constituents and for monitoring the in vivo metabolism of a substrate illustrates the potential usefulness of this isotope in biochemistry. The labeling of cellular components can have applications analogous to those now being used with *N*-oxyloxazolidine paramagnetic electron spin labels in membrane biochemistry, but with the advantage that the use of the internal ¹³C nuclear spin does not require external modification of biological material. The specific labeling of substrates can have numerous applications in in vivo metabolic studies.

In 1972, Sunney Chan and co-workers tied an isolated rabbit sciatic nerve at both ends to a capillary with filaments from nylon stockings and placed it in a 5-mm NMR tube containing modified Locke's physiological solution prepared in D₂O.⁸¹⁰ The 220 MHz ¹H NMR spectrum contained a water line that

could be resolved into two distinct peaks corresponding to extracellular water and intracellular water by adding Mn^{2+} to the bathing solution. In addition, the high-field region of the spectrum revealed a number of resonances ascribed to mobile phospholipids of the nerve.

Among the NMR-active nuclei, ^{31}P held particular potential for *in vivo* studies due to its 100% natural abundance and presence in many cellular constituents and metabolites. In 1973, Moon and Richards at the California Institute of Technology were the first to realize this potential, publishing 40.5 MHz pulse FT ^{31}P spectra of whole rabbit blood and hemolysates obtained from sonicated cells.⁸¹¹ Particularly interested in developing a convenient, nondestructive technique for determining intracellular conditions such as pH, they demonstrated that ^{31}P signals from 2,3-diphosphoglycerate and inorganic phosphate—estimated to be present in physiological concentrations of ≤ 7 mM—could be obtained after several minutes and their relative pH-dependent chemical shift behavior followed in hemolysates. In whole blood, both intracellular and extracellular inorganic phosphate resonances were observable, and the ~ 0.2 ppm difference could be used along with 2,3-diphosphoglycerate data to estimate the intracellular pH. The following year, Henderson et al.⁸¹² showed that cellular metabolism could be followed directly in intact human erythrocytes by measuring the intracellular levels of 2,3-diphosphoglycerate and inorganic phosphate.

In 1974, a group of investigators in Rex Richards's laboratory at Oxford University decided to take an important step forward: to see if an NMR spectrum of metabolites could be obtained in living excised tissue. They had available the first 7.5 T magnet and a state-of-the-art pulsed-FT spectrometer for observation of ^{31}P at 129 MHz. The instrument could detect phosphorus in 0.5 mM solution, clearly within the range of physiological concentrations. Previous experiments in collaboration with George Radda's group had included investigations of biological membranes and enzyme regulation mechanisms. The interest soon turned to ^{31}P studies of the glycolytic pathway in muscle extracts and thoughts of studying metabolism *in vivo*. Initial trepidations from members of the research team (about intact muscle possibly spoiling the field homogeneity or whether relaxation times would be too short) were overcome, and an intact muscle freshly excised from the hind leg of a rat was inserted into an NMR tube and immersed in Ringer's solution. Clearly resolved resonances were observed—assignable to ATP, phosphocreatine, inorganic phosphate, and sugar phosphate/phospholipid—and their change with time followed as the muscle tissue became anoxic, as shown in Figure 90.⁸¹³ Four members of the Oxford research team conducting these experiments—Hoult, Gadian, Radda, and Richards—provide in this volume personal reminiscences on the genesis of this experiment, and the synergism and excitement of the collaborating team. The results demonstrated that the intracellular pH fell as the muscle became anoxic and that the ATP levels decreased only after the phosphocreatine was depleted. The authors quickly recognized the significance of this work for the study of metabolism in muscle and submitted the paper for publication in *Nature*. In his historical sketch (*Radda, George K.: The Development of In Vivo NMR In Oxford*) Radda recalls:

The manuscript was rejected on the grounds that it described highly specialized experiments, unlikely to be repeated in other laboratories and of no general interest. I think this was the only time in my scientific career that I appealed against an editorial decision. I explained in my letter that we had talked about this

Figure 90 129 MHz ^{31}P NMR spectra of an intact muscle from the hind leg of a rat. Peak assignments: I, sugar phosphate and phospholipid; II, inorganic phosphate; III, creatine phosphate; IV–VI, adenosine triphosphate.⁸¹³ (Reproduced by permission of Macmillan Magazines Ltd)

work already in a number of places, particularly in the United States, and it created a great deal of excitement. The Editor accepted our argument and published the paper.

The first observations of living cells by ^{15}N were published in 1975. In these experiments, M. Llinas et al.⁸¹⁴ grew the fungus *Ustilago sphaerogena* on 95% ^{15}N -ammonium acetate and examined a freshly packed cell slurry in a 12-mm NMR tube via proton noise-decoupled ^{15}N NMR spectroscopy at 10.1 MHz. Some 120 000 pulses were required to obtain a spectrum with sufficient signal-to-noise ratio to observe several resolved resonances from compounds within the cell.

Studies on Isolated Cells and Organelles Gain Momentum

The initial studies outlined above were followed over the succeeding years with a veritable explosion of publications exploiting ^{13}C , ^{31}P , and ^1H as noninvasive probes of biochemical processes in intact cells and organelles. The study of isolated cellular preparations had a number of attractions, not the least of which was the ability to study *in vivo* processes with minimal modifications to the conventional NMR equipment available in the 1970s and early 1980s. In addition, the ability to study homogeneous cell cultures and to manipulate extracellular conditions created a fertile environment for basic research in areas such as cellular energetics, metabolic pathways, and membrane permeability and transport.

Many of the early publications emanated from Bell Laboratories and a group of researchers that included R. G. Shulman, G. Navon, S. Ogawa, K. Ugurbil, T. R. Brown, J. A. den Hollander, S. M. Cohen, and others. The work of this group is described by Shulman (*Shulman, Robert G.: My Years in NMR*) and serves as an illustration of the types of experiments conducted during this period on cellular preparations. Shulman and co-workers exploited the high resolution and sensitivity of a Bruker HX-360 spectrometer, which they estimated to provide a six-fold increase in signal-to-noise ratio over that in an XL-100. Their initial experiments⁸¹⁵ used ^{31}P NMR at 146 MHz in suspensions of

Figure 91 90 MHz ^{13}C NMR spectrum obtained within 1 min from a suspension of *E. coli* at 20°C 5 min after adding glucose enriched with ^{13}C at the C-1 position.⁸²⁰ (Reproduced by permission of the American Association for the Advancement of Science)

baker's yeast, and were followed by studies of Ehrlich ascites tumor cells, *E. coli*, rat liver mitochondria, and isolated rat liver cells to measure phosphate metabolite concentrations and internal pH, and to demonstrate the important point that pH gradients were created across the membranes when energized. These experiments branched into several research directions. Brown et al.⁸¹⁶ applied the saturation-transfer technique for the first time in vivo to determine exchange rates between inorganic phosphate and the terminal phosphate of ATP in *E. coli*; Ugurbil et al.⁸¹⁷ studied glucose metabolism in *E. coli* using ^{13}C -labeled glucose; Cohen et al.⁸¹⁸ followed the gluconeogenic pathway from ^{13}C -labeled glycerol in suspensions of isolated rat hepatocytes; and Barton et al.⁸¹⁹ used ^{13}C NMR and labeling techniques to study sugar metabolism in dormant and germinating yeast spores. Figure 91 illustrates the detailed information obtainable from the ^{13}C studies.⁸²⁰

Concurrent with this work, a number of laboratories began reporting ^{31}P investigations using preparations of cells and subcellular organelles. For example, Daniels et al.,⁸²¹ Casey et al.,⁸²² and Pollard et al.⁸²³ studied the internal structure and pH of bovine adrenal medullae chromaffin granules; Evans and Kaplan⁸²⁴ conducted a survey of phosphorus compounds present in human cancer (HeLa) cells grown from tissue culture; and Gupta et al.⁸²⁵ reported a procedure for determining the level of free Mg^{2+} in human red blood cells.

In 1979, the Bell Labs research team published a review of cellular applications, commenting that 'The ^{13}C and ^{31}P nuclei in many ways yield complementary data and, when used on the same system, supply a tremendous amount of simultaneous information about metabolic functions in vivo.'⁸²⁰ That same year at Oxford University, Styles et al. demonstrated a means of exploiting this potential by publishing details of a spectrometer and probe design that permitted the recording of interleaved ^{31}P and ^{13}C NMR spectra during a single experiment.⁸²⁶ They presented data on the metabolism of ^{13}C -labeled glucose by erythrocytes to demonstrate the advantages of the technique for simultaneous multinuclear monitoring of metabolic fluxes.

The use of proton NMR to study metabolites initially lagged somewhat because of problems with the intense water line and the multiplicity of resonances, including broad, but strong, background lines from less mobile constituents of the cell (membranes, etc.). In some instances the water could be removed by washing and re-suspension of cellular preparations in D_2O , but for most studies water-suppression methods were needed especially for pulse FT experiments. Selective

presaturation of the water resonance, as discussed in Section 10, was usually the method of choice in early work, but greatly improved methods eventually became available as improved instruments and techniques were developed. Van Zijl and Moonen⁸²⁷ provide a comprehensive review of methods, and we shall refer to some of these techniques in Section 16.

Methods to edit out broad lines began to appear in the mid-1970s. Brown et al. used a spin echo FT technique to eliminate spectral components with short values of T_2 ⁸²⁸ as shown in Figure 92 for human erythrocyte cells suspended in D_2O buffer. The sharp peaks appearing on elimination of the broad, dominant resonance of hemoglobin are assignable to mM concentrations of mobile intracellular species, such as glutathione. Figure 92 also shows the phase modulation of some resonances from homonuclear spin-spin coupling. This proved generally useful as an assignment tool (often in conjunction with spin decoupling) and also for monitoring enzyme-catalyzed deuterium exchange. Other similar editing methods were developed, as described in a 1984 review by Dallas Rabenstein.⁸²⁹

Erythrocytes were not the only intact cells studied by ^1H NMR. For example, Nicolau et al. studied normal and virus-infected chick embryo fibroblasts,⁸³⁰ Agris and Campbell reported an investigation of differentiation of Friend leukemia cells,⁸³¹ and Mountford and co-workers initiated

detailed investigations of membrane structure in intact non-transformed and malignant cells.⁸³² The surprising result in many of these studies was the observation of high-resolution spectra characteristic of plasma membrane lipids. This was contrary to the picture that had emerged from the large body of work on model phospholipid bilayers and natural membranes, i.e., that incomplete averaging of dipolar interactions leads to broadline ^1H spectra for membrane constituents (Section 10). In 1986, Bloom et al.⁸³³ published a method for observing the 'complete spectrum' of intact viable rat mammary adenocarcinoma cells by simultaneously determining the high-resolution (nondipolar-broadened) and broadline (dipolar-broadened) components. Their technique (which used Carr–Purcell–Meiboom–Gill and Jeener–Broekaert pulse sequences to separate the spectral components) was capable of identifying the percentage and type of protons associated with the high-resolution and dipolar-broadened spectra.

One aspect of research on isolated cells that attracted (and continues to attract) considerable attention was the exploitation of NMR techniques to discriminate between intracellular and extracellular substances and to study transport processes. In the early ^{31}P studies outlined above, the maintenance of a pH gradient across energized cellular membranes could be demonstrated by the simple observation of both internal and external inorganic phosphate resonances. In many cases it proved possible to dope the exterior medium of cellular preparations with shift reagents or relaxation agents to create the desired discrimination between intracellular and extracellular components.⁸³⁴ An elegant method introduced by van Zijl et al.⁸³⁵ made use of the apparent reduction in diffusion coefficient for intracellular molecules that results from restricted motion. They developed a more sophisticated version of the technique used by Stejskal and Tanner¹³⁸ to allow excellent discrimination between intracellular and interstitial NMR signals.

The use of cellular suspensions or packed cells, while simple from a procedural standpoint, created experimental difficulties. For example, very viscous solutions had to be used in erythrocyte suspensions (hematocrits >70) or the cells would settle during spectral accumulation.⁸²⁹ Also, the maintenance of cell viability including adequate oxygenation for aerobic cells, the uniform delivery of substrates or other physiological challenges, and the elimination of waste products were recognized problems with both suspensions or packed cells. A number of innovative techniques were developed to overcome these complications. In their 1977 ^{31}P study of metabolism in aerobic *E. coli* cell suspensions, Navon et al.⁸³⁶ used oxygen bubbles to oxygenate the cells and maintain them in suspension. To avoid introducing field inhomogeneity, they synchronized the bubbling with rf pulses. An alternative approach, introduced by Balaban et al.,⁸³⁷ relied upon the space in a 10-cm bore 4.3-T superconducting magnet to set up a 20-mm NMR cell chamber that used a hyperbaric atmosphere of oxygen over a stirred solution to achieve mixing and oxygenation during the NMR experiment.

In 1981, Ugurbil et al.⁸³⁸ published a technique for the continuous perfusion of intact cells during the NMR experiment, using 'anchorage-dependent' mouse embryo cells that naturally attach and thrive on dextran microcarrier beads. Cancer cells, in particular, were heavily studied in ensuing years with this approach, but not all cells attached well to the microcarrier beads and there was a loss in sensitivity as

the beads themselves filled much of the sample space. Jack Cohen, in his historical sketch (*Cohen, Jack S.: Recollections of Early NMR Applications to Proteins and Cells*), describes how he and David Foxall explored alternative approaches:

After some experimentation, we found that the best means was to make a very fine gel thread by extruding the liquid gel (mixed with cells) through a cooled capillary. This had the advantages that the gel could be packed with cells (thus retaining S/N) and the small diameter of the thread (0.5 mm) allowed effective access to the nutrients, as we showed by extensive diffusion studies. This method has now been applied for ten years and many successful studies of cancer cell metabolism have been published.

Many other perfusion methods were introduced in order to improve the applicability to particular cell types or experimental protocols, increase the NMR sensitivity or magnetic field homogeneity, and promote the long-term physiological stability of the cells during the NMR experiment. Although in vivo techniques for the study of intact animals have advanced dramatically over the last decade (as we discuss in the following sections), the physiological homogeneity of cell populations and the ability to control extracellular parameters in perfusion systems has resulted in the continuing use of these model systems as a means of improving the understanding of fundamental biochemical processes.

Perfused Intact Tissue and Organs

The pioneering 1974 study by Hoult et al. on intact skeletal rat muscle demonstrated the ability of ^{31}P NMR to measure intracellular pH, the complexation of ATP with Mg^{2+} , and to follow changes as the nonperfused tissue dies from anoxia. Reports soon followed of similar ^{31}P NMR studies on a broad range of muscle types, adrenal glands, developing frog embryos, and other tissues. One of the first problems to be tackled was the development of techniques to keep the extracted tissue alive during the several hours length of the NMR experiment. Dawson, Gadian, and Wilkie⁸³⁹ developed a probe that fitted into the Oxford 7.5 T spectrometer and not only allowed perfusion of small excised muscles with oxygenated Ringer solution, but also permitted electrical stimulation of the muscles and measurement of tension development at the same time as ^{31}P spectra were obtained. Britton Chance joined George Radda and his co-workers at Oxford to measure metabolism in a small rat heart that fitted within the 8-mm sample tube.⁸⁴⁰ At that time several other groups were also working on techniques to allow NMR measurements on whole perfused organs from mice or rats, which were suitably small to fit within the confines of available spectrometers. Don Hollis⁸⁴¹ describes the genesis of experiments at Johns Hopkins School of Medicine following a talk by R. G. Shulman, whom Hollis had invited to speak about ^{31}P NMR studies of *E. coli* metabolism:

After the talk Bill Jacobus, Shulman and I talked informally about our work while standing in the hall waiting for someone to fetch Shulman's coat ... Taking his lead from the Oxford study on frog leg muscle, Jacobus asked, 'Why can't we look at a living, beating animal heart and study its metabolism under various conditions when it is actually working?' I replied, 'I have the largest NMR probe now available commercially and the biggest sample it can take is only 15 mm in diameter. We would have to squeeze the heart and all of your plumbing into that small space.' 'Hell', said Jacobus, 'I can do that easily'.

We made a date to try it and the next day Jacobus and several of his co-workers showed up at my laboratory carrying boxes of rats, rolls of polyethylene tubing, bottles of nutrient solutions, tanks of oxygen, surgical tools and sutures. Besides these, they were pushing a cart loaded with an electrocardiograph set-up, a pacemaker, and other electronic gadgets. Within a few hours we had a small beating rat heart in the NMR machine, and we immediately saw what we had hoped for: a beautiful, clear, perfectly resolved spectrum of heart metabolism.⁸⁴²

Control of the heart rate in these experiments was achieved by tiny pacemaker leads sewn onto the heart muscle, and the individual heart beats recorded by means of a small water-filled latex balloon sewn into the left ventricle that transmitted the pressure from contraction through a polyethylene tube to a transducer external to the spectrometer.

These initial studies, which demonstrated that ^{31}P NMR could be used not only to monitor metabolism in the normal working heart, but also to investigate the effects of partial and total ischemia, were followed by ^{31}P NMR studies on other organ preparations including, for example, nonperfused hypothermic and blood-perfused rat kidneys as a model system for kidney transplants⁸⁴³ and ^{13}C NMR studies of gluconeogenesis from labeled alanine in perfused mouse liver.⁸⁴⁴ Very shortly thereafter, superconducting wide-bore magnets were developed allowing more room for perfusion apparatus as well as organs from larger animals. The range of reports on perfused whole organs broadened enormously over the following decade. One example, described by Bob Balaban in his historical sketch (*Balaban, Robert S.: Personal Perspective on the History of NMR*), gives a sense of the thrill of discovery that accompanied this research:

During this time the serendipity of the biological applications of NMR spectroscopy became very clear. In one of our earliest studies we performed a series of studies with ^{14}N NMR attempting to measure the concentration and distribution of urea in the intact kidney (with Mark Knepper). However, our studies revealed a very broad and not very useful urea ^{14}N resonance (exchange broadening), but an extremely sharp and intense resonance in the region of trimethylamines. After a week of library and telephone interviews, it was clear that no one knew what this compound was in the kidney in the 20–80 mM concentration! It turned out to be the oxidation product of choline, betaine, and its discovery started a new area of research in renal studies on the role and regulation of these organic osmolytes in the protection and function of the kidney.

The study of perfused organs continues to find applications today, despite the many technological developments discussed below that now permit NMR studies of intact animals and humans. In part, this is due to the ability to control more easily certain experimental conditions including the administration of labeled compounds.

High-Resolution NMR of Intact Animals

Intact, living animals had been studied by NMR, but only to obtain limited information. In 1968, Jackson and Langham built a shielded solenoid that provided a uniform field of 10 G and obtained the first NMR spectrum of a living animal.⁸⁴⁵ The proton NMR spectrum at 40 kHz of a live, anesthetized rat not surprisingly showed only a single broad resonance. In 1972, Weisman et al.⁸⁴⁶ conducted an important study in the emerging field of NMR in the study of pathology

when they measured T_1 in normal and malignant tissue in a living mouse. They overcame the restrictions of an NMR spectrometer designed for chemical samples by observing the tail of the mouse, which could be fitted into the NMR probe. A tumor implanted in the tail showed a T_1 value that was more than twice as long as that in normal tail tissue. Only crude localization was possible in this apparatus.

The high-resolution NMR spectrometers of the late 1970s were generally narrow-bore (5 cm) systems which were adequate for isolated cells or excised tissue and organs, but could not be considered for studies of intact animals. However, things were changing. By 1977, a 4.2-T 10-cm bore spectrometer had been developed by Oxford University in conjunction with Oxford Instruments, and was being used in Radda's laboratory for perfusion studies in the rat heart and kidney. This magnet had sufficient working space to allow the study of small whole animals, and ^{31}P spectra of a heart in a living, anesthetized rat were obtained with a coil implanted into the animal.⁸⁴⁷ However, efforts to obtain similar results from a rat kidney ran into problems with localization, since signals from nearby muscle could not be eliminated. Joe Ackerman, then a postdoctoral fellow in Radda's laboratory, describes in his historical sketch (*Ackerman, Joseph J. H.: Oxford Knights*) the origin of a better method:

I remember well the repeated unsuccessful attempts to pack gauze pads about the coil in an attempt to push the surrounding tissue out of the antenna coil's transmission/reception range. It was two in the morning, the jokes were getting stale and tempers a bit edgy when I realized the all too simple lesson in front of us: samples don't have to be inside the antenna coil to be detected. I walked out of the spectrometer room and down the hall to our office. This cramped space also served as the coil-design electronics laboratory. The first surface coil was wound. A simple tank circuit frequency-tuned and impedance-matched the surface coil to ^{31}P —80 MHz at 4.2 T. I returned to the spectrometer room to find even more gauze packed about the implanted kidney coil. Tom and Gordon were clearly fed up with the kidney experiment. They agreed to humor me. We put the surface coil on the rat thigh, the largest muscle group. One of us ventured that if we could just get enough ^1H tissue water signal to shim the field we might have a chance with the ^{31}P experiment. We were stunned, the ^1H FID was enormous. Shimming was remarkably easy. Tom, Gordon, and I quickly switched the spectrometer over to ^{31}P . Within minutes a beautiful muscle spectrum showing inorganic phosphate, phosphocreatine, and the α -, β -, and γ -phosphate resonances of ATP was in hand.

A paper describing the surface coil and its sensitivity was published in *Nature*.⁸⁴⁸ Figure 93 shows a ^{31}P spectrum obtained from a rat brain. As indicated, a convolution difference method was used to eliminate the broad ^{31}P resonance, primarily from bone.

In retrospect, surface coils had actually been used by other workers for specific purposes, for example by Jay Singer to measure blood flow⁸⁴⁹ as we describe in Section 16. However, their significance and detailed characteristics had not been explored. As shown by Ackerman and co-workers, a surface coil placed adjacent to an object detects signals from a region confined approximately to the coil circumference and to a depth equal to about the radius of the coil. High filling factors resulted in good signal-to-noise ratios. As such, the surface coil provided an extremely sensitive and simple method for observing high-resolution signals from regions localized near the surface of intact animals or in surgically exposed organs. The use of surface coils, according to Radda, 'transformed completely the possibilities of in vivo spectroscopy.' They

Figure 93 ^{31}P NMR spectra of the brain of an intact rat, obtained with a surface coil. (a) Observed spectrum. (b) Same as (a), with 400 Hz line-broadening applied. (c) Difference spectrum between (a) and (b).⁸⁴⁸ (Reproduced by permission of Macmillan Magazines Ltd)

have been utilized very widely since their introduction in 1980. Some 10 years later it was estimated they were being employed in more than 80% of the published *in vivo* NMR studies.

A surface coil can be used as a receiver only, or as both transmitter and receiver. In 1983, Bendall and Gordon introduced a technique which used to advantage the inherent inhomogeneity of the rf field B_1 generated by the surface coil over the roughly hemispherical volume adjacent to the coil. In simple one-pulse experiments, it had been shown that one could set the pulse length so as to obtain a 90° pulse—and thus maximum signal intensity—at a particular depth from the coil. Bendall and Gordon demonstrated that spin echo and inversion–recovery sequences, coupled with phase cycling, can provide markedly increased discrimination against sample regions where pulse angles differ from the ideal values.⁸⁵⁰ They coined the name ‘depth pulse’ to describe this selectivity.

Radiofrequency surface coils and depth pulses continued to provide an important means of spatial discrimination, but variation of the static field B_0 , rather than B_1 , across the sample soon furnished the principal means for carrying out localized NMR spectroscopy. Imaging techniques and other means to tailor the homogeneity of B_0 provided numerous effective approaches, as we shall discuss later. During the early 1980s, high-field, wide-bore horizontal superconducting magnets became available commercially, ushering in a new era for *in vivo* NMR. Field strengths of 2–4.7 T, with initially 30 cm and then 40–45 cm diameter bores, could be used to study animals the size of dogs or small sheep. The number of *in vivo* applications emanating from these animal systems in the succeeding decade has been enormous. Narrower bore systems at even higher fields (e.g., 7 T) also became available commercially.

High-Resolution Studies on Humans

By the time it became technically feasible to perform high-resolution NMR studies on human subjects, a considerable foundation of knowledge had been built from work on perfused cells, tissues, and organs, as well as intact animal models.

The first high-resolution NMR spectra of human subjects were obtained using the same horizontal, wide-bore superconducting magnets developed for animal experiments. Britton Chance managed to get his leg into an 18-cm bore magnet to obtain ^{31}P spectra.⁸⁵¹ According to George Radda, ‘the resolution was not very good, but Chance’s leg in the magnet impressed *PNAS*, where the first spectra were published.’

The capability for studying muscle metabolism in humans by NMR spectroscopy was quickly put to a clinical test by Radda and his associates in a study of a patient suspected to have a phosphorylase activity disorder termed McArdle’s Syndrome. The experimental setting was nonclinical, with the patient placing his forearm into the 30-cm bore of the 2 T magnet that was located in the Biochemistry Department of Oxford University. However, the results published in the *New England Journal of Medicine* in May 1981, were indeed clinically significant.⁸⁵² Using a ^{31}P surface coil to follow the intensity and position of the intracellular ATP, phosphocreatine, and inorganic phosphate resonances, the authors were able to demonstrate abnormal responses to ischemic exercise and establish a clinical diagnosis. This work signaled the beginning of an extensive program of medical applications of NMR by Radda’s group, which moved clinical studies to a new building at the John Radcliffe Hospital, and obtained a larger bore magnet. His historical sketch (*Radda, George K.: The Development of In Vivo NMR In Oxford*) describes the development of this work, which had involved some 4000 patient investigations by August 1993.

The work of Shulman’s group at Yale University is illustrative of research in another important area, ^{13}C NMR studies of glycogen metabolism disorders. Intracellular glycogen is sufficiently flexible that resolved ^{13}C resonances are obtained for this large polymer,⁸⁵³ and can be used to monitor glycogen concentrations *in vivo* in normal controls and diabetic patients. Such studies have technical difficulties including the low sensitivity of ^{13}C , rf power deposition during decoupling, and spatial displacement artifacts from the large chemical shift range. Nevertheless, as Shulman recounts in his historical sketch:

The insulin independent rate of glycogen synthesis has clinical consequences for the control of diabetes, suggesting that intense glycogen depleting exercise would help diabetics. These glycogen experiments illustrate how a definite result of a basic research program, i.e., the visibility of the glycogen ^{13}C NMR, can be developed to the point where *in vivo* NMR experiments can delineate the control of its synthesis. This allowed us to determine the nature of a serious illness and these studies suggested a means of controlling the disease.

Further advances in *in vivo* NMR spectroscopy are intertwined with the development of NMR imaging techniques, a subject that we treat in Section 13. We shall return briefly to a summary of some recent examples of *in vivo* spectroscopy in Section 16.

IMAGES BY NMR

NMR, discovered and initially developed as a technique for obtaining data of importance in physics, had been dominated from the mid-1950s by applications in chemistry, where it had revolutionized the methods used for the structure elucidation of organic molecules and biopolymers. As we have seen in the previous section, living systems, too, were investigated by NMR spectroscopy. But in the early 1970s NMR was to move into totally new areas, as methods were invented for obtaining *spatial* information that had immediate practical value in the fields of biology and medicine.

Zeugmatography

Magnetic field gradients have always been of importance in NMR. Early efforts were directed entirely toward minimizing such gradients in order to produce the largest feasible volume within the magnetic field that had adequate homogeneity for high-resolution NMR. With the development of suitable electric ‘shim’ coils to generate gradients up to fourth order in various directions, it was possible to compensate for many of the unwanted gradients of a large magnet and to achieve high overall homogeneity. Within this homogeneous field, it then became possible to deliberately apply a gradient (almost always linear) in a particular direction to permit the acquisition of certain information. For example, we saw in Section 4 that Herman Carr had, in 1951, applied a gradient across three pieces of rubber to simulate the effect of local chemical shift fields in ethanol. The Carr–Purcell pulse sequence could also be used to measure diffusion if a known linear field gradient was applied, a process that was improved by using a pulsed gradient, applicable only for a short, fixed period. Gabillard examined the NMR signal in simple glass and liquid objects on which a one-dimensional gradient was imposed,⁸⁵⁴ and Walters and Fairbank⁴¹⁴ used a field gradient to detect phase separation between ³He and ⁴He. In unpublished work at the National Institutes of Health, Kudravcev⁸⁵⁵ recognized that field inhomogeneity provided by static or alternating field gradients could be used to localize a volume of interest. All of these applications depended on the spatial variation of the NMR signal, usually along a one-dimensional gradient. Gradients had been used for other purposes, as well, as pointed out by Ralph Hurd in his article (*Hurd, Ralph E.: A Brief History of Gradients in NMR*).

In September 1971, Paul Lauterbur conceived the idea of using magnetic field gradients in a more elegant way—to obtain two- or three-dimensional spatial information about the distribution of magnetic nuclei in a sample placed inside an NMR coil and thus to create a ‘picture’ of the object by NMR. The Larmor relation $\nu_0 = (\gamma/2\pi)B_n$ ensured that the NMR frequency would precisely monitor the magnetic field B_n at the nucleus, so that if a linear gradient G is applied in the direction x , along with the large static field B_0 ,

$$\nu = (\gamma/2\pi)B_0(1 + Gx) \quad (4)$$

and the observed frequency can measure the value of x . Lauterbur realized that the homogeneity controls on an ordinary NMR magnet could be adjusted to provide a linear gradient in any one of the three orthogonal directions x , y , or

z , and by using combinations of these Cartesian gradients the overall gradient could be set in any chosen direction.

In his historical sketch (*Lauterbur, Paul C.: One Path out of Many--How MRI Actually Began*) Lauterbur describes the inspiration for his idea during a stay at NMR Specialities near Pittsburgh, after he had observed Leon Saryan, a graduate student with Don Hollis, carrying out relaxation measurements with excised tissue from rats (work that was described in Section 12):

I watched them being done, including the sacrifice of the rats, specimen dissection, and the NMR measurements, and was struck by the consistent differences obtained among various normal and malignant tissues. I knew, however, that biopsies were commonly done and examined by histologists, and I believed that NMR relaxation time measurements on tissue specimens were unlikely to contribute much to the rich variety of information available from optical microscopy. All of this information about the tissues was apparently there, however, within the living organism. Was there any way that one could tell exactly which location an NMR signal was coming from within a complex object? That same evening I realized that inhomogeneous magnetic fields labeled signals according to their spatial coordinates, and made a leap of faith to the conclusion that the information could be recovered in the form of pictures (we would now say that the inverse problem could be solved). I was so sure of this that I immediately went out and bought a notebook and had the idea witnessed.

The first page of that notebook is reproduced in Figure 94. Subsequent pages record further ideas on how to do such experiments. Over the next few months, Lauterbur worked out procedures for disentangling the data obtained from a number of experiments with gradients in different directions and, ‘after failing to convince various people and institutions that it was a good enough idea to patent’, he carried out a test of the ideas with a standard A–60 spectrometer.

Lauterbur submitted his initial work to *Nature* in October 1972 and eventually it was published, but not without some difficulty in convincing the editor of the potential importance of the work. Although his motivation for inventing this method had been primarily a desire to use NMR methods to image tissue in a living object, his paper emphasized the generality of the physical principle, which at first might seem to contradict the classical laws of diffraction. In general, the resolution obtainable from an electromagnetic wave is no better than its wavelength, so the use of radiofrequencies with wavelengths of meters to image in the range of millimeters might seem absurd to a classical optical microscopist. Lauterbur pointed out that the phenomenon here is quite different, and that it is the combined effect of the static magnetic field and the rf that leads to localization. He coined the term *zeugmatography* (from the Greek *ζεγγμα*, ‘that which is used for joining’) to describe the technique. After some interesting and amusing correspondence with the editor of *Nature*, as reproduced by Hollis,⁸⁵⁷ Lauterbur’s paper was accepted and appeared in March 1973.⁸⁵⁸

This paper illustrates the use of gradients in several directions and describes a way of generating two-dimensional images by back-projecting the one-dimensional ‘spectra’ produced from each gradient. An image of the test sample, two capillaries of water, which would fit within a standard 5-mm diameter NMR tube, was clearly reproduced as illustrated in Figure 95, and the effect of different relaxation times was shown by partial saturation. The relaxation time study was important in the context of using the method to investigate

Spatially Resolved Nuclear Magnetic Resonance Experiments.

The distribution of magnetic nuclei, such as protons, and their relaxation times and diffusion coefficients, may be obtained by imposing magnetic field gradients (ideally, a complete set of orthogonal spherical harmonics) on a sample, such as an organism or a manufactured object, and measuring the intensities and relaxation behavior of the resonances as functions of the applied magnetic field. Additional spatial discrimination may be achieved by the application of time-dependent gradient patterns so as to distinguish,

Paul C. Lauterbur

living systems, in view of the work described in Section 12 which had shown increased T_1 values in certain tumors, either excised^{805,806} or in situ.⁸⁴⁶ Lauterbur pointed out the potential for the method in the NMR of solids and liquids, with electron spin resonance, and possibly in other regions of the spectrum. His concluding sentence in the manuscript⁸⁵⁸ described the wide utility:

Zeugmatographic techniques should find many useful applications in studies of the internal structures, states, and compositions of microscopic and macroscopic objects.

In the production process, the words 'and macroscopic' were deleted from the final published article.

With only a standard NMR magnet available, Lauterbur was forced to test the method further with small objects. The first living animal to be imaged was a clam, 4 mm in diameter, which fitted into a standard 5-mm sample tube, and NMR showed the soft structure within the closed shell, the latter

not contributing to the proton NMR signal.⁸⁵⁹ By 1974, with a modified Varian DA-60 which had a larger magnet gap, he was able to display an image of the thoracic cavity of a living mouse.⁸⁶⁰ Two years later, he demonstrated T_1 changes in a tumor implanted in a mouse.

New Twists on Zeugmatographic Methods

Lauterbur's paper, possibly because of its title and general approach, attracted little attention in the NMR community, but his talks at several meetings served to alert NMR spectroscopists to the new method.

The International Society of Magnetic Resonance (ISMAR) held its triennial meeting in Bombay in January 1974. The potential importance of Lauterbur's short submitted paper was recognized by the conference organizers, and his talk was converted to a plenary lecture where it attracted the attention of Raymond Andrew, William Moore, and Waldo Hinshaw, all then at the University of Nottingham. After discussions among themselves, Hinshaw developed a novel approach in which he used time-varying gradients in the x , y , and z directions in which a single small volume experienced only a constant, homogeneous magnetic field.^{861,862} An NMR signal could be obtained only from this 'sensitive point' by taking the time integral of the FID, thus canceling out signals from time-varying fields. The sensitive point could be readily moved around the sample by varying dc currents in the three orthogonal directions and a 3D image was thus obtained. The Sensitive Point method was quite simple to implement and required no complex data processing, an advantage at that time, as described in Hinshaw's historical sketch (*Hinshaw, Waldo: Notes on the History of MR Imaging from my Perspective*):

One constraint we had in developing an imaging method was the lack of a computer. I did have access to Andrew's pulsed NMR spectrometer which had an analog output, and everything in the lab was analog. I spent evenings and weekends assembling clock motors and potentiometers and coils. Bill [Moore] provided constant encouragement. By April of 1974, we had produced the first images. With this work, we were the first group after Lauterbur to produce MR images. Bill and I applied for and were awarded the first patent on MR imaging, or as we called it then, NMR spin-mapping.

This method, however, was inefficient in discarding most of the potential signal and in requiring many repetitions to cover a volume of interest. Although the technique was improved to produce data from a 'line' rather than a 'point', it eventually gave way to more efficient methods.

An alternative method was proposed in 1974 by Garraway, Grannell, and Mansfield,⁸⁶³ who suggested the use of a selective pulse in the presence of a field gradient to excite only a narrow band of frequencies, hence a thin slice of the sample. Following ideas introduced by Tomlinson and Hill²⁹¹ (see Section 7), the exciting pulse was tailored to contain only Fourier components that fitted within the desired slice. A two-dimensional 'column' could be selected by repetition of this process, with the gradient rapidly switched to an orthogonal direction and the resultant signal read out by application of a static gradient in the third orthogonal direction. For the creation of 2D or 3D images, this method was soon supplanted by other, more efficient, techniques. However, as we shall see below, its application to one-dimensional slice selection has been very widespread. David Hoult^{864,865} pointed out that this

Figure 96 The basic idea of Fourier transform imaging.⁶⁸⁵ (Reproduced by permission of Academic Press)

technique as originally proposed suffered from loss of signal from the rapid dephasing of magnetization that occurs during a long selective pulse applied concurrently with a strong field gradient, but the signal can be recovered with the addition of a gradient reversal to rephase the spins and create an echo.

Meanwhile, at the 15th ENC (Experimental NMR Conference) in Raleigh, North Carolina, in April 1974, Lauterbur presented a short talk entitled 'Spatial Resolution of NMR Signals'. Richard Ernst, who was in the audience, had been thinking about Jeener's unpublished work on two-dimensional NMR (see Section 11) and realized that time-domain experiments with switched magnetic field gradients could provide an alternative to the back-projection method in obtaining NMR data across a plane or throughout a three-dimensional volume. This led to the concept of 'NMR Fourier Zeugmatography' published by Kumar, Welte, and Ernst⁶⁸⁵ in 1975. The principle of the method is illustrated in Figure 96. Initially, a 90° pulse rotates the magnetization to the xy plane, where it precesses in the presence of three orthogonal linear magnetic field gradients, g_x , g_y , and g_z , applied in succession. The FID is sampled in the third time interval as a function of t_z . The experiment is repeated for a full set of equally spaced t_x and t_y values. The three-dimensional Fourier transform of the FID is a measure of the spatial spin density and provides the three-dimensional image of the sample. In the terminology that was later developed, the first two gradients encode the phase of the signal, based on its frequency (hence position along the operative gradient) and the period during which the gradient is imposed.

Ernst moved rapidly to test the idea in a two-dimensional regime, using two tubes of water, a Bruker SPX4-100 spectrometer, a Varian 15-inch magnet, and a Varian 620/L-100 computer with 12k memory. As Anil Kumar relates in his historical sketch (*Kumar, Anil: Development of Two-Dimensional NMR--My Perception*),

Ernst wrote a few subroutines, Dieter Welte wrote others and I did the experiment. The gradients were applied by switching off the current in the linear shim coils of an electromagnet. A crude 64×64 matrix image of two tubes of water was printed on a teletype by digitizing the intensity into blanks, dots, and alphabets. We laughed at the experiment and published it without patenting.

Figure 97 The first two-dimensional Fourier transform NMR image of two tubes of water. The intensity intervals are indicated in increasing order by the symbols (blank), •, *, A, B, C, D, and E.⁶⁸⁵ (Reproduced by permission of Academic Press)

[Actually, as Ernst recounts, he later filed a patent (March 1975) and assigned it to Varian Associates for whom he was a consultant.] The two-dimensional Fourier zeugmatogram thus obtained is shown in Figure 97. For this plot, the total intensity range was divided into eight equal intervals and a teletype character was assigned to each interval. As in 2D NMR spectroscopy, the Fourier imaging concept has been extended to the third dimension.

During the 1970s, as various methods were being tried, it became apparent that the 2D/3D FT method of Ernst et al. was an efficient procedure, but the necessity of incrementing the period for applying the phase-encoding gradient (for 2D imaging) or gradients (for 3D) could lead to distortions in the image, since inhomogeneities in the static field cause a phase error that varies as the phase-encoding time changes. At Aberdeen, Edelstein et al.⁸⁶⁶ developed a simple variation of the Fourier imaging method to circumvent these problems with the instruments available at that time. Instead of varying the phase-encode time, they maintained a constant time but incremented the magnitude of the phase-encode gradient. Since this process can be pictured as introducing a phase twist to projections along a particular axis, they coined the name 'spin warp' method. The 'constant time' spin warp very quickly replaced the original 2D FT imaging method for practical use.

While the term 'zeugmatography', together with other names, such as 'tomography', have largely given way to the simple and descriptive 'imaging', the method used for most of the commercial development of magnetic resonance imaging

(as we shall see later) has relied on the basic zeugmatographic concept of the application of linear magnetic field gradients. For medical applications, the 2D/3D FT approach, as modified into the spin warp method, has largely been the method of choice. However, a full 3D data set involves many repetitions and usually consumes too long a time for practical use. Moreover, as Hinshaw comments in his historical sketch, 'radiologists preferred the images that could be obtained from a set of separately acquired slices'. The use of several parallel slices became the generally preferred procedure, with slice selection almost invariably carried out by the method of Garroway et al., incorporating Hoult's gradient recalled echo as described above.

Hoult later developed an interesting variant of the imaging method, 'rotating frame zeugmatography', in which one of the static field gradients in the observation plane is replaced by a gradient in the rf field.⁸⁶⁷ The method has been used in special circumstances and has been especially valuable for localized spectroscopy, for example in ^{31}P NMR with a surface coil.⁸⁶⁸ However, the technique is not widely employed as a general imaging method.

From Diffraction in Solids to Imaging in Liquids

As we saw in Section 8, Peter Mansfield was one of the most active workers in developing multiple pulse techniques for line narrowing in solids during the late 1960s and early 1970s. In 1972, he began to think about the possibility of using NMR to determine atomic structure in a solid in which the dipolar interactions had, in effect, been removed by multiple pulse methods. Allen Garroway's account in his historical sketch (*Garroway, Allen: N., Origins of MRI--A Personal View*) of the first discussion of the idea is informative:

One day in the early summer of 1972 as Grannell and I were having morning coffee in the Physics tea room, Peter Mansfield pulled up a chair and said, in essence: 'I've had this really crazy idea. It seems that one could measure atomic separations in crystalline materials by imposing a magnetic field gradient and observing the resultant NMR diffraction pattern'. Grannell rolled his eyes. From my experience in pulsed gradient diffusion, I volunteered that the required magnetic gradients would need to be immense and, further, that the alignment and the perfection of the crystal would need to be of the order of crystal lattice dimensions. ...

As Mansfield relates in his historical sketch (*Woessner, Donald E.: In a Maze in NMR*), the idea was pursued only sporadically for some time because of other work and his departure for a sabbatical in Heidelberg. Garroway's initial estimates were correct: calculations showed that for diffraction in an atomic lattice a field gradient of ca. 1000 G cm^{-1} would be required, and the multiple pulse methods would have to produce lines two orders of magnitude narrower than were then obtainable. However, Grannell used a multiple pulse sequence to reduce dipolar couplings in an artificial one-dimensional lattice created from layers of camphor crystal separated by layers of cardboard. Mansfield and Grannell were able to obtain a one-dimensional interferogram to a resolution of better than 1 mm, as illustrated in Figure 98.⁸⁶⁹ The work was presented at a Colloque AMPERE⁸⁷⁰ in Krakow, Poland in September 1973, a meeting which brought together all the major figures in the field of line narrowing in solids (see Section 8). Ulrich Haeblerlen, in his historical sketch, (*Haeblerlen, Ulrich: The Early Days of Multiple Pulse NMR*)

Figure 98 Fourier transform of the transient response to a multiple pulse sequence from layers of camphor. (a) Three layers, no magnetic field gradient. (b) Three layers, gradient of 0.77 G cm^{-1} . (c) Five layers, gradient of 0.77 G cm^{-1} .⁸⁶⁹ (Reproduced by permission of the Institute of Physics)

describes the presentations by Waugh, Pines, Vaughan, and many others, and goes on to say:

And Peter Mansfield what did he talk about? He began with reflection symmetry in [multiple pulse] sequences but soon turned to NMR diffractometry. In retrospect he talked and speculated about spin imaging and actually showed pictures of phantoms! Literally nobody took him seriously. What a mistake.

At the conclusion of Mansfield's talk, John Waugh mentioned Lauterbur's paper on zeugmatography, which Mansfield, Garroway, Hinshaw, and others had not previously noticed. In his historical sketch, Mansfield describes his initial reading of that paper soon after the Krakow meeting and 'the stark contrast between our two approaches to NMR imaging'. Mansfield's emphasis in this early work continued on crystals and other regular structures. He pointed out that 'NMR diffraction could be useful at the macroscopic level for microscopy in biophysical systems with regular, or approximately regular macroscopic structures, e.g. cell membranes and filamentary or fibrous structures'.⁸⁷⁰ Mansfield and Grannell pursued the idea of NMR diffraction and microscopy in solids and in less regular samples, including glass spheres in water.⁸⁷¹ They examined the theory and reported one-dimensional responses and 2D images obtained by projection-reconstruction techniques. By 1975, however, Mansfield and his co-workers had broadened the scope and were directing their attention to switched gradient methods with selective-pulse excitation⁸⁶³ to define a strip within the slice and obtain an image a 'line'

at a time.^{872,873} With this method they published, in 1977, a cross-sectional image through a human finger—the first image to reveal anatomical detail in a live human subject.⁸⁷⁴ The emphasis was on decreasing scan time so as to be able to study biological samples effectively.

In 1977 Mansfield published a new method, which would eventually be named ‘echo-planar imaging’ (EPI).⁸⁷⁵ This technique utilized his previously developed method for slice selection but then obtained imaging information from an entire slice with one excitation pulse followed by a string of echoes that resulted from a very rapid and repeated switching of field gradients. The idea for this approach, as he points out,⁸⁷⁵ could be traced in certain ways to his previous study of periodic structures using Fourier transformation in a continuous time domain, whereas here the complementary situation of a continuous structure was represented by a periodic time function (the echoes).

EPI makes severe requirements for strong and rapidly switched gradients, which were not easily attainable. Nevertheless, within a year Mansfield and Pykett had obtained crude images of a phantom⁸⁷⁶ and of anatomical features.^{877,878} By 1981, Ordidge et al.⁸⁷⁹ had presented the first real-time moving images, which demonstrated the potential for ‘freezing’ cardiac motions. Mansfield and his group continued to make incremental improvements in the methods, and with the development of actively shielded gradients⁸⁸⁰ (as we shall see in Section 16) they were able to overcome many of the practical problems associated with rapidly switched gradients. Meanwhile, former Mansfield students and co-workers advanced EPI techniques in a number of laboratories and companies in several countries. Only in the early 1990s did EPI begin to compete commercially with the more conventional methods based on spin warp FT zeugmatography.⁸⁸¹

FONAR and Related Methods

As we saw in Section 12, Raymond Damadian’s observation of lengthened relaxation times in excised mouse tumors had introduced the hope of a new diagnostic method for malignancy based on NMR data. Although Damadian’s early papers in this area were limited to the study of excised tissues, his paper in 1971⁸⁰⁵ suggested that ‘NMR techniques combine many of the desirable features of an external probe for the detection of internal cancer’, and in 1972 he filed a patent application for using NMR to detect pathology (including cancer) on the basis of differences in relaxation times from normal values. In attempting to develop an instrument to carry out such measurements, Damadian initially bypassed the new imaging methods based on the application of linear field gradients but opted instead to design a magnet in which only a small volume would have adequate homogeneity for NMR. The homogeneity would then deteriorate rapidly outside this volume so that little NMR signal would be observed from the remainder of the sample. Damadian referred to the method as field focusing NMR and coined an acronym FONAR.^{882,883} Like Hinshaw’s initial Sensitive Point method, FONAR had the advantage of simplicity in terms of data processing but the serious disadvantage of measuring only a small volume at a time and thus requiring a long time for a scan through a sample of significant size. Moreover, the homogeneous volume occurred in only one place in the magnet and could not

readily be moved by electrical current adjustments, as could the ‘sensitive point’, hence FONAR required that the sample itself be moved to a different position to obtain data from each volume of interest. As pointed out by Damadian⁸⁸⁴ and Hollis,⁸⁴¹ the procedure is reminiscent of early NMR work in which the probe was moved to locate the ‘sweet spot’ homogeneous volume.

Damadian and his co-workers published the first FONAR image of the thoracic cavity of a live mouse in 1976⁸⁸⁵ and also showed an image of a mouse in which a tumor had been implanted in the upper thorax. The resolution was estimated at 3 mm. Meanwhile, in Japan, Abe, Tanaka, and their co-workers⁸⁸⁶ proposed a similar method by using pairs of reversed Helmholtz coils to tailor the field homogeneity in a conventional electromagnet. [Chen and Hoult⁸⁵⁶ describe and analyze this method and several other early techniques that were intended for imaging.] Crooks et al. used iron shims attached to the pole caps of an electromagnet to generate a locally homogeneous volume and obtained data from a rat by moving the animal and the rf coil through the homogeneous region.⁸⁸⁷

All of these methods were useful in obtaining initial data and in exploring various approaches, but they were dropped as practical imaging methods because of the complexity of moving the sample and the excessive time required to obtain data. The concept survived somewhat longer in obtaining NMR *spectroscopic* data from a localized volume. In fact, in 1980 Oxford Research Instruments introduced a commercial instrument using more sophisticated homogeneity control under the name ‘Topical NMR’,⁸⁸⁸ designed particularly to measure metabolic processes by ³¹P NMR in a volume of interest inside a living subject. (‘Topical’ in this context refers to a local place, not a surface, as is sometimes used in medical terminology.) During the mid-1980s, however, further development of imaging methods permitted more effective definition of local volumes for in vivo spectroscopic studies, as we shall see in Section 16.

From Phantoms and Fruits to Human Imaging

Each of the imaging methods began with the study of inanimate objects, often tubes of water (‘phantoms’ in medical parlance). Much of the early developmental work advanced more rapidly with the use of such well-defined and controllable samples, but the major interest was in studying living animals and humans, and there were many early efforts to do so. As mentioned above, Lauterbur studied the first living animal, a tiny clam. Fruits and vegetables became the object of study in many laboratories since their internal structures were already well known and precise details could be readily verified after completion of the NMR experiment. Images of lemons, onions, peppers, and many other fruits and vegetables were duly recorded and reported in papers and at conferences.

For several years the available magnet sizes precluded the study of large objects, but small animals or portions of animals were frequently examined. In addition to some early measurements mentioned in the preceding sections, other groups examined mice, rats, and a rabbit. These results were important in exploring the various parameters that are under the control of the investigator. In particular, the mobility and relaxation times of water in different tissues could be

exploited to improve image contrast, and pulse sequences were developed to optimize differences in T_1 by using an initial inversion–recovery sequence and T_2 by a spin echo method. The increasingly faithful images of anatomical structure aroused the interest of a medical audience, but human images were clearly needed to demonstrate the potential value of NMR imaging.

The first live human NMR image was published by Mansfield and Maudsley⁸⁷⁴ when they used a line scan to examine the internal anatomy of a finger, an appendage small enough to be inserted into a standard NMR magnet. Contrast between bone, bone marrow, nerve, artery, and other tissues was demonstrated. Soon Andrew et al. used the multiple sensitive point method and a larger gap electromagnet to image a hand,⁸⁸⁹ while Hinshaw, Bottomley, and Holland examined Bottomley's wrist and discussed potential medical uses.⁸⁹⁰

Serious application to most anatomical studies required a magnet capable of holding a human being. The necessary scale-up from traditional NMR sample sizes was dramatic, but the magnitude of the magnetic field was reduced correspondingly. Most early efforts were directed toward electromagnets with an air core, designed for a field of about 0.1 T (4 MHz for ^1H NMR). Damadian and his co-workers constructed a superconducting magnet of 53-inch diameter and used it at 0.05 T (2 MHz) with his FONAR method to obtain the first image of a human chest.⁸⁸² With the low-field, point-by-point method, resolution was understandably poor, but major features such as the heart and lungs could be readily identified. Shortly thereafter, Mansfield et al.⁸⁹¹ observed the first image of the human abdomen, and Clow and Young reported the first NMR image of a section through a human head.⁸⁹² Features such as the eyeballs and ventricles in the brain were clearly visible. This work was done at EMI, a British electronics company, and represented the beginning of commercial development of NMR imaging, a topic we discuss in the next section.

By 1980 Moore and his colleagues at Nottingham were able to demonstrate one advantage of NMR imaging over X-ray computed tomography (CT) in showing the first sagittal and coronal sections of a human head.⁸⁹³ In another paper the same year, they showed that NMR images could reveal a wide range of pathology in the head and commented on the 'dramatic ... new advance in neuroradiological capability with its potential impact on clinical management'.⁸⁹⁴ Their clinical results provided examples that included tumors, aneurysms, circulatory malformations, and chronic sinus infection. Meanwhile, in 1980 as well, Damadian showed a number of cases of carcinoma in the chest.⁸⁹⁵

A New Tool for Radiology

As we observed in Section 2, once it had been demonstrated (largely by physicists) that NMR could be used to solve real chemical problems, the chemists, as Martin Packard put it, 'took over' in the late 1950s. A similar situation obtained in the early 1980s with NMR imaging. While many questions still had to be answered and much development work had to be done, radiologists and other clinicians became quite interested in the potential of the method, and several companies specializing in equipment for medical diagnosis sensed a possibly lucrative new market and began development projects.

In England, EMI (Electrical and Music Industries, Ltd.), which had pioneered X-ray CT and had a growing business with this modality, began work on NMR imaging in 1974 primarily as a protective measure to explore all possible competitors to CT. The story of this development is recounted in an interesting historical sketch by Ian Young (*Young, Ian R.: EMI's Venture into NMR--An Industrial Saga*), which describes the initial work with a 0.1-T electromagnet and an instrument and computer that provided images by back-projection with 3–6 min of data acquisition. As Young says, 'We began to acquire phantom images with some degree of respectability in late 1977, early 1978, but an attempt to image a volunteer head was quite disastrous, resulting in something like a frayed rabbit with drooping ears.'

In a cooperative project between EMI and the British Department of Health and Social Security, the system was converted to a superconducting magnet as technology was developed by Oxford Instruments to produce such 1-m bore magnets. Derek Shaw's historical sketch (*Shaw, Derek: From 5-mm Tubes to Man. The Objects Studied by NMR Continue to Grow*) provides an amusing perspective from the magnet manufacturer's viewpoint:

In the late 70s, a radically new group of customers (radiologists) and companies (the diagnostic imaging manufacturers EMI, GE, Philips, Picker, Siemens, ...) became interested in NMR. The key factor at this stage was the magnet. Working, as I was at this period, for Oxford Instruments was in some ways like being in an Alan Ayckbourne play. Diverse characters from all the medical imaging companies would come in to discuss their own 'secret ideas' and specify their own unique magnet requirements, resistive/superconducting, 0.15 T/1.5 T, four coil/six coil ... These requirements were often the same as the company before, leading to the need for considerable 'political sensitivity'.

The EMI magnet was designed for 0.3 T but preliminary data at 0.15 T, obtained when the system was set up in Hammersmith Hospital, looked good enough to Graeme Bydder, the radiologist in charge of NMR studies, that he insisted on maintaining that field strength and beginning to examine patients. As Bydder relates (*Bydder, Graeme M.: Magnetic Resonance at Hammersmith Hospital*) from the perspective of a practicing radiologist,

There were other difficulties. The Department of Radiology was not only installing a new NMR system but also a CT system, and there was no radiologist in the department with any clinical experience with either technique. The new CT system was bought from a rival company (Siemens) and was providing very high quality images of greater spatial resolution than the NMR system. The NMR machine itself was single slice only, and each of these slices took seven minutes to reconstruct (the CT system took only five seconds). It was difficult to see how it would be possible to even complete a single examination of the head (16 slices) with NMR in less than three hours. The patient handling of the NMR system was acutely uncomfortable, the water cooled valve amplifiers were highly unreliable, and the sole copy of the operating manual went missing soon after installation and was never found again.

Nevertheless, progress was made with the cooperation of the radiologists, the engineers from EMI, and the patients, who 'seemed prepared to put up with any amount of discomfort and inconvenience in the interests of research'. The advantages of the inversion–recovery sequence for obtaining T_1 -weighted images were demonstrated in time for their presentation at an important meeting at Wake Forest University, Winston-Salem,

NC, where all the leading imaging groups met in October 1981 (see Figure 99).⁸⁹⁶ It became apparent that each group had its own problems and discouragements, but substantial progress was being made.

The Hammersmith group continued to advance with the development of a spin echo method to examine pathology in the brain. Meanwhile, at the University of California in San Francisco, Alexander Margulis organized an NMR imaging project with Leon Kaufman and Larry Crooks, together with Jay Singer from nearby Berkeley (where he had pioneered in studying flow by NMR). Margulis (*Margulis, Alexander R.: How NMR Was Started at the University of California, San Francisco (UCSF)*) describes the way in which funding was obtained and progress was made toward a new Radiologic Imaging Laboratory. After developing techniques with animal studies, they started human imaging in 1981 with a 0.35-T magnet that had been purchased by Pfizer, and continued development in collaboration with NMR Dasonics when Pfizer left the imaging business. Crooks's historical sketch (*Crooks, Lawrence E.: Field Strength Selection for MR Imaging*) describes the thought that went into the purchase of the magnet and the decision as to how high a frequency could be employed without encountering problems with rf absorption by the subject. He goes on to say:

Our contacts at Pfizer Medical Systems were pleased with the superconducting magnet idea. One thought it sounded so sexy that no doctor would pass it up. The usual concern we encountered within our Radiology Department was 'You're going to have cryogenics in the hospital!'. That did not seem to concern Pfizer much and we proceeded to visit Oxford and IGC to review the designs so that Pfizer could assess the companies. Based on business and technical aspects, Pfizer decided to order a magnet from Oxford for placement in our laboratory. Oxford at the same time built a similar magnet for EMI that was placed in Hammersmith Hospital. It worked before ours, but at 0.15 T.

By April 1981, Crooks and colleagues had obtained their first head image by a line scanning method, but they soon converted to 2D FT in order to improve the signal-to-noise ratio and reduce scanning time. They rapidly improved their techniques and learned how to optimize contrast from a knowledge of relaxation times. Their impressive results at 15 MHz^{897,898} 'began a race to ever higher field strengths'.

Meanwhile, Waldo Hinshaw, who had invented the Sensitive Point method of imaging and had later worked with Moore and Andrew at Nottingham in further developments of imaging techniques, took up an appointment in 1978 at the Massachusetts General Hospital to set up imaging research in the MGH radiology department. With financial support from the health products firm Johnson and Johnson (J&J), Hinshaw began development of a clinical imaging instrument but soon realized that the development could be better pursued in an industrial environment. In 1979 he moved to Solon, OH and began working with J&J's subsidiary, Technicare, as he relates in his historical sketch (*Hinshaw, Waldo: Notes on the History of MR Imaging from my Perspective*):

Technicare was a very aggressive engineering-driven medical imaging company and was the ideal environment for the rapid development of an MRI product. We put together a team of about 14 engineers and, within 9 months, had a small system producing images at 1.5 T. We had the mistaken idea that it would be easier to develop this small system first. We also wanted to explore as early as possible the clinical utility of spectroscopy. This 'small animal' system went to the MGH and enabled the team there to publish several early papers.

Technicare developed and manufactured several imaging systems based on whole body, resistive, water-cooled magnets, then switched to superconducting magnets from Oxford Instruments, first at 0.5 T and then 0.6 T. Hinshaw's sketch describes a number of technical innovations by the Technicare staff before the company was sold to General Electric in 1986.

The General Electric Company's Medical Systems Division (GEMS) had started late in the X-ray CT field but had built a large CT business. Not until 1982 did they become really interested in the NMR imaging market, but meanwhile the GE Corporate Research and Development Center in Schenectady began to explore the fields of imaging and spectroscopy. With the arrival in 1980 of Paul Bottomley and Bill Edelstein, who had had significant experience in Nottingham and Aberdeen, respectively, work began, first on a 0.12-T electromagnet system, and in 1982 on a superconducting magnet that had been targeted at a 2-T field strength but actually barely made 1.5 T. This magnet was intended for spectroscopy, since the prevailing opinion at the time was that imaging would not be effective at so high a field because of problems with rf penetration. Bottomley's historical sketch (*Bottomley, Paul A.: The Development of High-Field NMR Imaging: 0.12 T to 1.5 T*) describes the evolution of the views of the scientists as they found that they could get good images at 1.5 T, and of the GEMS managers as they developed a market strategy based on the better sensitivity and resolution of the high field.

By November 1982, they had obtained images of relatively poor quality but good enough to show at the meeting of the RSNA (Radiological Society of North America) that month. By February 1983, Bottomley and Howard Hart did better. As Bottomley says,

With the magnet fixed and Howard's head inside the slotted tube resonator, I began obtaining fantastic images with 256 × 256 resolution in 4 mm slices and 100 s scan times. I was ecstatic. My notebook that day is scrawled with expletive next to the polaroid prints. There was no one to show (Howard was magnet-bound). I dragged in the cleaner: 'Isn't this the most incredible picture you've ever seen?' We published in the *Lancet*. We knew the images were better than anything else around the time.

During the next year or so many arguments would ensue on the relative virtues of GE's high field (1.5 T) versus the lower fields (0.3–0.6 T) that were then produced by most other companies. Ultimately systems with a range of field strengths would be sold for various applications, but GE's high-field strategy paid off: in the nine years from the first shipment of 1.5 T systems to the end of 1993 GE sold over 1350, and most other companies adopted 1.5 T as one of their options as well (Figure 100).

Meanwhile in Germany, Siemens, which was a major player in the medical imaging field, started to look seriously at NMR imaging as early as 1977, when the Corporate Research Laboratory considered the construction of large magnets and the generation of magnetic field gradients. A project to develop imaging capability was begun by the Medical Engineering Group in 1978, with Arnulf Oppelt and Andrew Maudsley as the principals, later joined by Wilfried Loeffler. By May 1979 they had constructed a test bed using an Oxford Instruments 0.1-T resistive magnet, and by the end of the year had obtained an image of a green pepper. By March 1980 they had imaged a human head, and later that year began examining patients. Siemens went on to develop a full line of clinical imaging instruments, including one with a 2.0-T magnetic field.

Figure 100 NMR has become best known to the public through its use in medical imaging. A typical whole-body 'scanner' is shown. Courtesy of General Electric Co

Philips Medical Systems Division began work on NMR imaging in 1973 shortly after Lauterbur's initial publication, when Rob Locher started a one-person project with a small-bore magnet. By 1978, work in the Philips Physics Laboratory and advances elsewhere persuaded Philips to undertake a full-scale effort under Andre Luiten, Locher, Cees van Uijen, Jürgen Heinzerling, and Jan den Boef. Their first head scan was carried out in 1980, and by 1983 Philips had tested a 0.15-T system at the University Hospital in Leyden. Philips went on to develop higher field instruments and to become a major manufacturer of NMR imaging equipment.

Some of the major high-resolution NMR manufacturers (as described in Section 6) also made ventures into the imaging field. Starting in the early 1980s, Bruker developed a full range of imaging capability, from microimaging accessories for high-resolution spectrometers to large-bore research instruments for imaging and spectroscopy of animals and humans. Varian started only in the mid-1980s to develop animal systems, initially in cooperation with Technicare and later in a joint venture with Siemens. General Electric Medical Systems purchased the high-resolution NMR business from Nicolet (as noted in Section 6) and with that addition developed animal spectroscopy and imaging systems before selling this phase

of its business to Bruker. Later, SMIS (Surrey, England) developed systems for imaging and spectroscopy in animals.

The explosion in commercial NMR imaging activity is reflected in a 1984 review by Battocletti.⁸⁹⁹ His comprehensive compilation of organizations using or building NMR imaging systems by 1983 lists some 20 separate groups. Among the industrial enterprises not already discussed above are the Fonar Corporation (Melville, NY), founded by Raymond Damadian, which began with instruments that were based on the FONAR technique and designed specifically to measure T_1 values. Later the Fonar Corporation developed and currently sells clinical instruments using more conventional imaging methods. They have concentrated particularly on permanent magnet systems at low to moderate (0.6 T) field strength. In England, Picker International took over the NMR imaging business from EMI and expanded to a manufacturing facility in Highland Heights, OH. Picker has become a major manufacturer of clinical NMR imaging units. In Finland, early work by Sepponen and Sipponen was based on a 60-cm bore system operating at 0.17 T. These efforts led to a commercial venture, Instrumentarium, which markets an imaging system based on a 0.1-T resistive electromagnet. The

French company, CGR, moved into NMR imaging in the mid-1980s and marketed instruments in Europe before transferring that line of business to GE in a major corporate realignment. In Haifa, Israel, Elscint Ltd. advertized an early superconducting system operating at 0.35 T and subsequently developed a wide range of scanners.

Four Japanese companies entered the NMR imaging business over the course of several years. Shimadzu and Hitachi have concentrated particularly on relatively low-field instruments. Otsuka acquired Chemagnetics (as noted in Section 6) and Phospho-Energetics, a company that had been formed specifically to exploit *in vivo* NMR spectroscopy. Otsuka developed a compact 1.5 T head-only unit. Toshiba began NMR imaging development in Japan, then acquired Diasonics around 1990 and broadened their research and manufacturing efforts. Advanced NMR Systems was formed in 1988 by Ian Pykett and Richard Rzedzian, both from Peter Mansfield's laboratory in Nottingham, largely to develop and commercialize echo planar methods. In the early 1990s they began offering an EPI accessory to GE's 1.5 T instrument.

Biomedical Magnetic Resonance Meetings

Following the early symposia on NMR imaging at Vanderbilt University in 1980 and at Bowman Gray Medical School, Wake Forest University in 1981, a group of early leaders in the field agreed on the formation of a society to bring together basic scientists and clinicians interested in the new discipline and to hold annual interdisciplinary meetings. Paul Lauterbur, Gerry Pohost, Alex Margulis, Britton Chance, and Tom Budinger served as an Executive Committee to convene a Board of Directors meeting at the 1981 symposium, and the Society of Magnetic Resonance in Medicine (SMRM) was born. Its first scientific meeting, held in Boston in August, 1982, drew a large attendance and served as the prototype of annual meetings in North America and western Europe. With broad representation in membership and among the officers from scientists interested in imaging and *in vivo* spectroscopy, development of new methods and clinical applications, the Society's meetings grew larger and benefited from interaction with and support by companies that manufactured NMR imaging equipment.

Meanwhile, others had become interested in the potential of NMR imaging, including Sharad Amtey, a medical physicist who had not been involved in research in NMR. He organized a workshop on the subject in Houston in February 1981, and at the Bowman Gray meeting later that year, Amtey and others planned for the Society for Magnetic Resonance Imaging (SMRI), which was formally organized in 1982 and held annual meetings beginning in 1983. The early meetings were poorly attended as compared with those of the SMRM, but gradually attained viability.

Discussions between the SMRM and SMRI resulted in a merger of the two organizations in January, 1994. The first meetings of the combined societies were held in Dallas in April, 1994 and in San Francisco in August of that year. After temporarily using the designation Society of Magnetic Resonance (SMR), the organization decided, in late 1995, to adopt the name International Society for Magnetic Resonance in Medicine (ISMRM).

Other companies have been fashioned to develop specific applications of NMR imaging and/or *in vivo* spectroscopy, and new enterprises are continually being formed. Our summary here is not exhaustive but illustrates the vitality in the commercial application of NMR imaging.

'MRI' Arrives

In the early 1950s, Jim Shoolery and Emery Rogers introduced the term 'NMR spectroscopy', partly to emulate the then popular IR spectroscopy, but also to avoid the word 'nuclear' which had some poor connotations. In the early 1980s, NMR imaging as a medical technique became increasingly familiar to the general public. Its proponents feared that the ominous 'N' would create storms of controversy as the large magnets were sited. Moreover, 'nuclear' also suggested to hospital personnel that this might be another aspect of Nuclear Medicine Departments. So with general agreement among radiologists and NMR imaging manufacturers (but not without resistance from old-time NMR spectroscopists!), *MRI* became the commonly used term for imaging. *MRS* is often used for spectroscopic applications, and *MR* is the generic abbreviation in medical circles.

By October 1987, sufficient clinical data had been obtained for the National Institutes of Health in the United States to convene a Consensus Conference, in which a 'jury' of radiologists and other clinical experts could assess the state of the art and make recommendations on optimum uses of MRI. The following excerpts from the Conference Statement⁹⁰⁰ highlight the prevailing views:

Even in the short period of its use, it has proved to be unusually rewarding in the detection, localization, and assessment of extent and character of disease in the central nervous, musculoskeletal, and cardiovascular systems. In the brain, for example, it has a proven capacity to define some tumors and the plaques of multiple sclerosis provided by no other technique. It is a competing imaging method in the evaluation of many other organs. Additional prospective studies comparing MRI with other diagnostic methods are essential in those areas where the method has shown promise but where its precise role has not yet been defined. This consensus development conference does not purport to include all of the applications of MRI to the pediatric patient, a subject that will require separate consideration. . . . The full potential of MRI has not been reached, and continuing refinement of equipment, contrast agents, and software may be anticipated. . . .

The final sentence quoted was prophetic. MRI has become widely available and is regarded as an indispensable diagnostic modality. New generations of magnets have been developed at both higher and lower magnetic fields for specific purposes. Faster scanning methods have become available and the quality of images has steadily improved. Moreover, imaging methods have been used to study function as well as anatomy, and imaging principles have been used for localized *in vivo* NMR spectroscopy. We shall return to an exploration of a few of these more modern developments in Section 16.

PROTEIN STRUCTURES BY NMR

By the early 1980s high-resolution NMR instruments and methods had advanced to the point that very complex

problems in molecular structure could be solved. The vast armamentarium of 2D techniques could be brought to bear on the structure elucidation of organic molecules; inorganic systems could be studied by almost every conceivable magnetic nuclide; and biopolymers, such as proteins, nucleic acids, and complex carbohydrates, could be studied in far greater detail than heretofore. In this short history, it is impossible to discuss even superficially the impact that NMR now has in all these areas.

In this section we focus on one area—protein structure. NMR has contributed in major ways to the study of other important problems involving various types of biopolymers, as well as smaller organic molecules, but the methods used are largely the same kinds of 2D NMR techniques that we have discussed in Section 11. However, for the determination of the three-dimensional structures of folded proteins, the complexity of the problem (previously not amenable to solution by NMR methods) has driven the development of new techniques that have met with spectacular success.

Assignments and Interatomic Distances in Proteins

As we have seen in Section 10, NMR had made significant contributions to our knowledge of the molecular structure and conformation of all types of molecules of biological interest. However, until the development of new approaches during the early 1980s, NMR was not capable of providing a three-dimensional structure of a biopolymer that specified the spatial location of its atoms. Only X-ray crystallography provided that information, and then solely for molecules that formed crystals of suitable quality. Moreover, X-ray crystallography, while clearly still the ‘gold standard’ for structural determination, often fails to provide important information on dynamic processes that alter conformation in solution.

High-resolution NMR in solution has long furnished in a qualitative way just the sort of information where X-ray crystallography is weak. Its use to determine secondary and tertiary structure in proteins depended, however, as Oleg Jardetzky points out in his article (*Jardetzky, Oleg: NMR in Molecular Biology—A History of Basic Ideas*) on overcoming three obstacles: *Sensitivity*, *Resolution*, and *Rules of Interpretation*. By the late 1970s NMR spectrometers were available with adequate sensitivity to study proteins at reasonable concentrations, and ^1H NMR frequencies of 400–500 MHz permitted the resolution of most resonance lines in small proteins where it was clear that chemically identical amino acid residues could be distinguished by differences in chemical shifts caused by secondary and tertiary structure. Interpretation of the spectra, however, depended first on being able to assign each resonance to a specific amino acid residue along the polypeptide chain, the sequence of which was already known from independent data.

Two double resonance techniques had long been used to establish proximity of protons—spin decoupling in some form to identify resonances from nuclei that are spin coupled, and the nuclear Overhauser effect to distinguish protons close in space. In fact, Gibbons et al.⁹⁰¹ had suggested a combination of INDOR and NOE to make sequential assignments of resonances in a peptide, but the method really came into use only during the latter part of the 1970s when Kurt Wüthrich and his co-workers embarked on a major, and ultimately

successful, effort to develop and generalize the sequential assignment of proteins.

Gerhard Wagner, in his historical sketch (*Wagner, Gerhard: NMR of Proteins*) provides an insight into the experiments carried out by Andreas Dubs, an undergraduate, on basic pancreatic trypsin inhibitor (BPTI) that initiated development of the sequential assignment technique:

As the primary work of his thesis, Andreas measured NOEs from the well-resolved slowly exchanging amide protons. When using short irradiation times, there was usually a single H^α resonance that showed a much larger NOE than anything else did. Only after a lengthy inspection of the BPTI model did we detect the almost trivial fact that the H^α of the preceding residue was generally nearest to an H^N , and that other H^α protons were a significantly larger distance away. We could show analytically that the initial slope of NOE build-up curves of truncated driven NOEs were directly proportional to r^{-6} and could be related to molecular structure. This identification of the sequential $d_{\alpha\text{N}}$ NOE, together with the intraresidue connectivities obtained from spin decoupling, quickly led to sequence specific assignments for 15 β -sheet residues. At the same time, we became aware of different sequential NOEs in helices and established an initial statistic of characteristic distances in β -sheets and helices.

The one-dimensional sequential assignment approach was followed soon thereafter by 2D techniques, as discussed in the following section, that yielded publication in 1982 of the first complete assignment of a protein spectrum, that for BPTI.⁹⁰²

Wüthrich’s historical sketch (*Wüthrich, Kurt: NMR Structures of Biological Macromolecules*) provides a lucid account of the systematic evolution of his laboratory’s work in using NMR methods for protein structure determinations. While the initial work was carried out only with proteins whose structure was already known from X-ray crystallography, it became clear that the approach could be applied to small proteins whose amino acid sequences were known but whose three-dimensional structures had not been established.

An important advance in understanding the intensity build-up in the transient NOE and in avoiding effects of spin diffusion was made by Gordon and Wüthrich⁹⁰³ in 1978. As additional NOE data accumulated, Wüthrich and his co-workers realized that NOE data could provide the key information needed to estimate proton–proton distances between amino acids that are far apart in the linear sequence but in close proximity because of protein folding. A critical assumption, one that is still a point of contention many years later, is that the folded protein may be treated as a rigid body with a single correlation time for rotation. While clearly an approximation, this assumption served as a working hypothesis, and the ultimate success of NMR structure determinations has provided support for the conjecture. Obtaining the data with the 1D NMR methods that were then in use and interpreting them in a systematic way presented almost insurmountable challenges, but the emergence of 2D NMR provided the critical boost needed for clearing this hurdle. By 1984, the first de novo 3D structure of a small globular protein, BUSI (bull seminal plasma inhibitor), a protein with 57 amino acids and a molecular weight of 6000, had been completed.^{904,905}

Critical to the determination of protein structures from NMR data were suitable computational methods for relating interatomic distances to Cartesian coordinates in three dimensions. The development of several such distance geometry methods in a number of laboratories around the world is a story in

itself that is beyond our scope here. Likewise, refinement of structures with techniques of restrained molecular dynamics and simulated annealing, and development of procedures for integrating these with NMR data in efficient computer analyses, constitute an impressive set of accomplishments that have been reviewed in a number of places.^{906–908}

The use of NMR for 3D structure determination of proteins was soon taken up and developed further by several other laboratories, including those of Clore and Gronenborn, Wright, Kaptein, and other groups such as those of Jardetzky, Campbell, and Markley, who had long been involved in protein NMR studies. However, many X-ray crystallographers and biochemists were quite skeptical that reliable structures could, in general, be determined in this way. The NMR approach gained widespread credibility as a result of a unique competition, as described by Wüthrich in his historical sketch:

When I presented the NMR structure of BUSI in some lectures in the spring of 1984, the reaction was one of disbelief and suggestions that our structure must have been modeled after the crystal structure of a homologous protein. In the discussion following a seminar in Munich on May 14 1984, Robert Huber proposed to settle the matter by the independent determination of a new protein structure in his laboratory by X-ray crystallography and in my laboratory by NMR. Each of us received 100 g(!) of pure Tendamistat from Dr. L. Vértessy at Hoechst AG and, as is well documented in the literature, this project was started. Dr. Allen Kline had arrived in Zürich in March 1984 and agreed to join the competition. We obtained complete resonance assignments and the secondary structure determination by the end of the summer 1984. In late 1985, virtually identical three-dimensional structures had been obtained in solution⁹⁰⁹ and in crystals.⁹¹⁰ ... The fact that a genuinely novel type of polypeptide fold had been determined in the NMR structure of Tendamistat apparently convinced many of the critics that NMR could actually do the job.

The Role of 2D NMR

In 1976, soon after Ernst's initial publication laying out the field of 2D NMR, he and Wüthrich began collaborative work to apply such methods to protein NMR. As new 2D experiments were designed and computational facilities for handling 2D data were improved, they considered the implications for protein studies, but meanwhile the initial protein structural studies were carried out with conventional 1D methods. It was clear that the 2D approach would be better, with techniques such as COSY substituting for selective decoupling in tracing chemical bonding paths and NOESY providing the critical NOE data throughout the spectrum at one time. Kuniaki Nagayama describes some of the practical problems in implementing these ideas in his article (*Nagayama, Kuniaki: The First Protein Two-Dimensional (2D) NMR*). A 10 mM sample of BPTI (basic pancreatic trypsin inhibitor) served as the sample, run at 60°C at 360 MHz, to obtain well-resolved 2D *J* spectra of 20 methyl groups. A short paper describing this advance was submitted to *FEBS Letters* but was soon rejected 'due to the lack of any biological relevance'. The work was soon accepted by another journal.⁹¹¹

2D NMR rapidly became *the* way to carry out NMR studies for protein structure determination. All the three-dimensional structures discussed in the preceding section were obtained

primarily with 2D NMR data. In addition to the 'Felgett advantage' of carrying out the equivalent of many decoupling or NOE experiments concurrently, the 2D method permitted more sophisticated approaches. For example, the suppression of solvent water signal could be carried out much more effectively, thus permitting studies in H₂O rather than D₂O, and allowing observation of signals and NOEs from amide protons and bound water.

The total range of 2D methods discussed in Section 11 became available—TOCSY, HOHAHA, NOESY, ROESY, and many modifications of COSY. Along with concurrent (and very important) advances in computational technology, computer speed, and data storage capacity, the 2D approach to protein NMR permitted a number of groups to make rapid progress in determining 3D structures. Old-fashioned 1D concepts were not forgotten, however; use of the Karplus relation to estimate dihedral angles from measured coupling constants played an important role in improving the precision and accuracy of the NMR structures. Figure 101 gives examples of the gradual refinement in the quality of structures over a period of about five years.⁹¹² In general, larger amounts of data from more complex NMR experiments have led to increasing numbers of restraints in the computer-driven process of structure determination, which translate into a more precise structure. In addition, it has been possible to carry out a larger number of independent calculations, each beginning from a random coil form, so that there is greater confidence in the average structure that is determined.

The process worked well for proteins up to 10 kDa or so, but as larger molecules were attacked, problems occurred. There are simply too many NMR lines and, even though spectrometer frequency advanced from 500 MHz to 600 MHz, overlap of 2D resonance contours became a problem. In addition, the larger molecules tumbled more slowly and linewidths increased. An example of the difficulty in interpreting the complex maze of overlapping peaks is given in Figure 102 which shows a NOESY spectrum from *S. nuclease*, a protein of about 17.5 kDa. It looked as though the NMR determination of structures had reached the limit of applicability.

3D and 4D NMR Come to the Rescue

One of the virtues of 2D NMR as compared with 1D NMR is that resonances can spread across a plane instead of being confined to a linear plot. It had long been recognized that 2D concepts could readily be extended to more dimensions but, as discussed in Section 11, two principal problems occurred. The first was to maintain acceptable digitization in the indirectly detected dimensions, as this requires the use of either very narrow spectral windows or a very large number of increments—for 3D, $n_1 \times n_2$, where n_1 and n_2 are the numbers of sampling points in the two indirectly detected dimensions. The second was to devise experiments that provided useful information with good sensitivity. Building on the published 3D studies of a smaller protein, Vuister et al.⁹¹³ demonstrated the power of nonselective 3D homonuclear NMR even when the digital resolution was lower than in the corresponding NOESY and HOHAHA–TOCSY 2D NMR spectra. Their NOE–HOHAHA experiment was applied to a relatively large protein, pike parvalbumin, containing 108 residues. The 3D spectrum (illustrated in Figure 103)

Generation	1st	2nd	3rd	4th
Example	Purothionin	BDS-1	BDS-1	Interleukin-8
Restrains/residue	~7	~10	~13	~16
RMSD: Backbone	1.5 Å	0.9 Å	0.7 Å	0.4 Å
RMSD: Total	2.0 Å	1.2 Å	0.9 Å	0.9 Å

Figure 101 Illustration of the progressive improvement in the precision of NMR structure determinations with increasing number of experimental constraints.⁹¹² (Courtesy of G.M. Clore and A.M. Gronenborn)

reportedly contains over 50 000 cross peaks and recording the data required about a week of measuring time.

Homonuclear 3D experiments involve two transfers of magnetization, each of which typically is less than 20% efficient, and generate an enormous number of cross peaks as indicated above. These two factors tend to make the 3D experiment considerably less sensitive than its 2D analogs, thus requiring concentrated samples. Groups at Abbott Labs and NIH concentrated on the development of **heteronuclear** 3D, separating the conventional 2D spectrum into a third dimension according to the frequency of ^{15}N or ^{13}C . This type of experiment includes a heteronuclear magnetization transfer step that is nearly 100% efficient and merely resolves the resonance overlap present in the 2D spectrum. This approach requires proteins that are uniformly enriched with ^{15}N and/or ^{13}C . Fortunately, development of recombinant

Figure 102 The 500MHz ^1H two-dimensional NOESY spectrum of *S. nuclease*. (Courtesy of D. A. Torchia)

DNA technology during the 1980s made it a fairly routine matter in many instances to over-express a particular protein in a bacterial 'factory' and produce the protein with $^{15}\text{NH}_4\text{Cl}$ as the only source of nitrogen. Likewise, uniformly ^{13}C -enriched glucose can be used as the source of carbon.

An early example of the use of such methods was in *S. nuclease*, which gave the uninterpretable NOESY spectrum of Figure 102. With the addition of an HMQC step to separate the resonances according to ^{15}N chemical shifts, the NOESY spectrum suddenly became readily interpretable. Figure 104 shows two planes from a 3D spectral plot which show clear discrimination of NOESY peaks.⁹¹⁴

Further uses of heteronuclear 3D methods, carried out with more modern techniques such as use of pulsed magnetic field gradients, clearly established the utility of 3D spectroscopy. In favorable cases, high-quality 3D spectra on labeled proteins can be recorded in less than 1 h. The urge for the unambiguous interpretations of the spectra of larger proteins prompted the addition of another dimension in the NMR experiments. The first four-dimensional NMR spectrum, published by Kay et al.⁹¹⁵ in 1990, dramatically improved the resolution. The power of the technique was demonstrated by the application of four-dimensional (^{13}C - ^{15}N) edited NOE spectroscopy to interleukin 1β , a protein of 153 residues. The NOEs between

Figure 103 The three-dimensional NOESY-HOHAHA spectrum of the protein parvalbumin.⁹¹³ (Reproduced by permission of Academic Press)

NH and the aliphatic protons were first spread out into a third dimension by the ^{15}N chemical shift of the amide ^{15}N atom, and subsequently into a fourth dimension by the ^{13}C chemical shift of the directly bonded ^{13}C atoms.

Other 4D techniques have been successfully employed. For example, the NIH⁹¹⁶ and Abbott groups⁹¹⁷ independently developed 4D $^{13}\text{C}/^{13}\text{C}$ -separated NOESY experiments to resolve ambiguities in NOESY spectra arising from interactions between amino acid side chains. Before pulsed field gradients were available, such spectra tended to be cluttered with artifacts, but by using a very intricate phase cycling scheme, Clore et al.⁹¹⁸ managed to obtain useful spectra. With the use of gradients, it is now clear that if uniformly ^{13}C - and ^{15}N -labeled proteins can be obtained, recording such spectra is practical, and high quality 4D spectra can be obtained on relatively dilute samples (1–2 mM) in about 3 d.

A New Approach to Sequential Assignments

The use of NMR data to derive three-dimensional structural information in proteins rests on the ability to assign each proton resonance to a specific amino acid residue. Limitations in the existing procedure for the sequential assignment of the polypeptide chain became apparent as investigators tackled larger proteins and those that are less receptive to NMR study. For example, the α -helical sections of proteins have relatively poor chemical shift dispersion, and unfavorable dihedral angles often result in small values of $^3J_{\text{H-H}}$ between C_α and amide protons, thus inhibiting the coherence transfer essential to establishing sequential assignments. The availability of proteins that are uniformly enriched in both ^{13}C and ^{15}N , together with the ability to record heteronuclear

3D spectra, convinced Ad Bax and co-workers that coherence transfer experiments that operated via the relatively large one-bond H-C-N-H couplings would be worthwhile, and they developed a set of such experiments designated by the coupling patterns, as illustrated in Figure 105. In his historical sketch (*Bax, Ad: NMR of Ethanol and Interferon- γ*), Bax describes the genesis of these methods and concludes:

Primarily due to the creativity and persistence of Lewis Kay, we were finally able to make the triple resonance experiments work, and using the new 3D data, Mitsu Ikura was able to complete his backbone calmodulin assignments shortly thereafter. Of course, we were tremendously impressed by our own accomplishments and were anticipating rave reviews when we submitted our results to the journal *Biochemistry*. To the contrary, the paper was initially rejected. Such ‘complicated experiments’ requiring the very expensive ^{13}C labeling were deemed to be of no practical interest!

As has happened in many other instances, however, the journal editors reconsidered, the paper was published,⁹¹⁹ and the new triple-resonance procedure became the basis for future resonance assignments in the protein backbone. Similar methods of coherence transfer using one-bond H-C-C-H couplings were developed for assignments in protein side chains by Fesik et al.⁹²⁰ and Kay et al.⁹²¹ Along with these techniques, new methods have been developed for measuring small coupling constants even with the rather broad lines that characterize proteins, and there has been a renaissance of ‘Karplus-type’ relations to estimate dihedral bond angles. In one interesting paper (the authorship of which reminded some observers of the famous paper on the origin of chemical elements by Alpher, Bethe, and Gamow⁹²²), Bax, Max, and Zax showed how small two-bond and three-bond C-C couplings could be measured in proteins in the 15–20 kDa range.⁹²³

NMR in Structural Biology

With NMR techniques capable of handling proteins up to 30 or perhaps 40 kDa, and with spectrometers ranging up to 750 MHz, NMR has become a true rival of X-ray crystallography in providing three-dimensional structures of proteins (and other biopolymers as well). More importantly, however, NMR has become a partner of crystallography in providing complementary information on dynamic processes. For example, NOE measurements have thrown considerable light on the hydration of proteins. Water molecules have been located in the interior of proteins, entirely in accord with results from X-ray crystallography, with residence times of 10^{-2} to 10^{-8} s. In addition, surface hydration has been detected by NMR with residence times below 1 ns.⁹²⁴

The mechanism and pathways by which a polypeptide chain of random conformation folds into the compact structure of a globular protein has been probed by hydrogen/deuterium exchange of peptide NHs. By taking advantage of the fact that the rate of such exchange increases by orders of magnitude with an increase in pH but is severely inhibited by hydrogen bonding or solvent inaccessibility in a highly structured region of a protein, Udgaonkar and Baldwin⁹²⁵ and Roder, Elöve, and Englander⁹²⁶ pioneered a method for using NMR to study the exchange of specific protons in a protein. These groups and others have determined the kinetics of various steps in

Figure 104 Two adjacent planes from the 3D HMQC-NOESY spectrum of *S. nuclease* uniformly enriched in ^{15}N .⁹¹⁴ (Reproduced by permission of the American Chemical Society)

the folding process and have been able to monitor transient intermediates. The contribution of NMR to the study of protein folding has recently been reviewed.⁹²⁷

Other dynamic processes and their impact on protein function have also been investigated. For example, the protein calmodulin binds calcium ions in two globular domains that are connected in the X-ray structure by a long α -helix. Measurements of ^{15}N relaxation times showed that this helical region is highly mobile and serves as a 'hinge' for the somewhat independent motion of the two domains.⁹²⁸ NMR studies showed that a 26-residue random coil peptide with high affinity for calmodulin adopts an α -helical conformation in the bound form. The complete three-dimensional structure of the complex⁹²⁹ showed that the two domains of calmodulin, which are far apart in the crystalline structure, clamp around the helical peptide to form an egg-shaped complex. Thus, the

flexibility found in the linker region is critical for the ability of calmodulin to bind to its targets.

In the calmodulin complex, the spectrum of the bound peptide could be observed selectively and its NOE interactions identified by means of a spectral filtering technique that discriminated between ^{12}C -attached protons in the peptide and ^{13}C -attached protons in the fully enriched protein.⁹³⁰ The Wüthrich laboratory, which had previously worked on the development of heteronuclear filtering procedures,⁹³¹ used analogous methods to establish the structure of a 68-residue *Antennapedia* homeodomain with a 14 base pair DNA duplex and to locate the recognition site in the DNA major groove.⁹³² Likewise, Clore, Gronenborn, and co-workers⁹³³ used isotope filtering to determine the structure of a complex between a 16 base pair DNA fragment and the binding domain of the protein GATA 1. In 1994, Oleg Jardetzky and co-workers⁹³⁴ published the structure of a *trp* repressor-operator DNA complex which

Figure 105 Techniques for sequential assignments in $^{13}\text{C}/^{15}\text{N}$ -enriched proteins. (a) Approximate values of some one-bond and two-bond coupling constants used for coherence transfer. (b)–(e) Schematic diagrams of the nuclei that can be correlated in different experiments. (Courtesy of A. Bax)

represents the largest protein–DNA complex studied thus far by NMR (a 25 kDa protein plus a 20 base pair DNA fragment). They made effective use of selective deuteration and isotope editing to permit separation and assignment of resonances in this large complex.

NMR IN MATERIALS SCIENCE

Over the past 20 years the field of Materials Science has gradually emerged in an effort to integrate physics, chemistry, metallurgy and other disciplines in focusing on the relation of the properties of solid materials to their overall structure, not only their chemical composition. With the development of line narrowing techniques for studying the NMR of solids and the invention of NMR imaging, NMR is making increasingly important contributions to materials science as a useful method for nondestructive evaluation and testing. There is hope that a more detailed understanding of internal microscopic motions as monitored by NMR relaxation times, for example, may be of value in predicting macroscopic properties such as the strength of polymers. In this Section we illustrate a few of the types of studies that have been made and highlight some of the

advances in NMR methods that have been required to carry out these investigations.

Molecular Environment and Dynamics

Small molecules can often be studied by normal high-resolution NMR methods in apparently solid materials if, in fact, they retain adequate mobility. For example, water in a gel is known to have a relatively narrow line since it moves rapidly through the matrix formed by the gel. Such small molecules have been added to porous solids to serve as probes of the environment. ^{129}Xe , with a spin of $\frac{1}{2}$, is a particularly attractive probe since it is spherical itself yet has a high polarizability which is reflected in large chemical shifts. Several groups have used ^{129}Xe as a probe to study the formation of zeolites or the symmetry of a cavity in a zeolite or clathrate. For example, Dybowski and co-workers⁹³⁵ used this technique to follow the removal of template molecules used in the production of zeolites, while Ripmeester et al.⁹³⁶ studied the nearly spherical cavities in xenon hydrate clathrates and structurally related clathrasils. The sensitivity of the ^{129}Xe probe of a clathrasil structure is illustrated in Figure 106, where the relatively sharp high-field line arises from xenon trapped in the large cavity of cubic symmetry while the low-field line reflects the lower symmetry (threefold) of xenon trapped in the smaller cavity. Fraissard's historical sketch (*Fraissard, J.: A Look at Solid Catalysts by NMR*) describes his use of ^{129}Xe and concludes:

By means of this technique it is possible to determine the dimensions and the form of the internal free volumes of zeolites without knowing their structures; to reveal structure defects produced, for example, by dealumination, and to determine their characteristics; to calculate the short-range crystallinity, as opposed to that determined by X-rays; to follow the mechanism of the synthesis and crystallization of zeolites during their preparation; to locate cations in the zeolite structure and to follow their migration or change in their environment depending on various factors; to locate any 'encumbering' species, for example, adsorbed molecules, extra-framework species, coke formed during catalytic cracking reactions, etc.; to determine the dispersion of metals (particularly when the particles are too small to be seen by electron microscopy) and the distribution of the molecules adsorbed on the particles (as opposed to the main coverage); to compare the diffusion of species as a function of the size of the zeolite 'windows'. This technique can also be applied to any microporous system (amorphous solid, polymer, clay, etc.). This list of applications is certainly not exhaustive.

The potential applications of ^{129}Xe and the quadrupolar nucleus ^{131}Xe have been broadened by a dramatic improvement in sensitivity resulting from laser optical pumping introduced by Happer et al.⁹³⁷ The hyperpolarized ^{129}Xe has a magnetization enhanced by about 10^5 as compared with normal thermal equilibrium and can be used as a probe in some of the applications described above, as well as in biological imaging studies of, for example, mouse lungs, blood, and tissue.⁹³⁸ Hyperpolarized ^{131}Xe , but not ^{129}Xe , shows a splitting of its resonance resulting from collisions with the container wall in a nonspherical container,⁹³⁹ suggesting that the quadrupolar nucleus might also serve as a useful probe of molecular structure.

Instead of a probe molecule that moves through the solid, the movement of magnetic polarization by spin diffusion can

Figure 106 ^{129}Xe spectra of a clathrasil [$136\text{ SiO}_2 \cdot 16(\text{CH}_2)_4\text{O} \cdot 8\text{Xe}$] at (a) 376, (b) 295, (c) 251, and (d) 220 K as the structure changes from tetragonal to cubic. The high-field peak from ^{129}Xe in 0.75 nm cavities is unaffected, whereas the low-field peak from 0.57 nm cavities changes from a shape characteristic of a nonaxial shielding tensor to that of an axial tensor.⁹³⁶ (Reproduced by permission of the Royal Society of Chemistry)

be monitored. From the rate of spin diffusion, the size and intimacy of the microstructural domains can be monitored in a heterogeneous sample such as a copolymer. For example, Spiess and co-workers⁷⁸³ examined a polystyrene–polybutadiene blend and observed morphological heterogeneities of 2.5 nm, a size that cannot readily be discerned by other techniques such as electron microscopy. The nature of the morphological structure can often be related to the material's strength and other macroscopic properties.

NMR Imaging in Solids

While molecular motions and spin diffusion are suitable for studying small-scale properties, NMR imaging can be used to investigate processes occurring on a larger scale. The diffusion of liquids into polymers or porous solids can be monitored by conventional imaging techniques. One of the very early applications of NMR imaging was carried out by Moore and his co-workers at Nottingham,⁹⁴⁰ who used slice-selective imaging to monitor the dynamics of the internal water content distribution in porous inorganic materials such as gypsum and Portland limestone during capillary inflow. Later, Blackband and Mansfield⁹⁴¹ used a similar imaging method to make quantitative measurements of the diffusion of water into solid blocks of nylon, while Weisenberger and Koenig⁹⁴² employed the FLASH method⁹⁴³ to measure the penetration of solvents into poly(methyl methacrylate). Fast imaging methods

are needed to cover the diffusion rate of such solvents as methanol and acetone. The NMR method was shown to have distinct advantages over other techniques in permitting an entire measurement to be carried out with one sample in a nondestructive manner and in permitting the observation of inhomogeneous diffusion. Similar imaging methods have been used to follow the reaction as an adhesive sets⁹⁴⁴ and to observe changes in local properties of elastomers when they are deformed. Meanwhile, Blümmler and Blümich⁹⁴⁵ showed that NMR imaging provides a simple method for assessing the aging of elastomers and to observe phase separation, with resolution in favorable cases as small as 30 μm .

In Section 17, we shall see further examples of the imaging of mobile phases in solid materials such as sandstone and soils.

NMR Imaging of Solids

Standard imaging methods could be used for studying mobile phases in solids, but imaging of the solid itself presented greater problems since line narrowing techniques must be applied in many instances. For some solids with small magnetic dipolar interactions, such as hydroxyapatite in bone (with all the organic matter extracted), magic angle spinning sufficed to narrow lines. In fact, when dipolar interactions are not too great and the sample can be spun rapidly without distortion, Cory and Veeman found that MAS is generally a better method for imaging than multiple pulse techniques.⁹⁴⁶ However, for most samples multiple pulse methods have been employed, sometimes in conjunction with MAS, for ^1H imaging while cross polarization/MAS has been the method of choice for imaging ^{13}C and other rare, less-sensitive nuclei.

A key feature to permit imaging in a rotating sample is that the magnetic field gradients required for imaging must rotate synchronously with the sample. The basic idea was patented by Wind and Yannoni in 1981,⁹⁴⁷ but implementation was carried out by Cory and Veeman only several years later.^{948,949} The rotating gradient technique relies on monitoring the rotor frequency and using this frequency to generate sinusoidal x and y gradients in quadrature.

Work during the 1970s demonstrated one-dimensional profiles in solids, but the first 2D imaging was developed by Chingas, Miller, and Garroway⁹⁵⁰ in 1986. They carried out a ^1H 2D FT experiment by using the pulse sequence shown in Figure 107. MREV-8 is applied during the evolution period to narrow the lines and a 'storage' period, in which the magnetization is moved to the z axis, facilitates gradient switching. They demonstrated the utility of the method by obtaining an image of a tube of neoprene rubber surrounding a sample of adamantane. By changing the experimental parameters, they were able to discriminate between the two materials on the basis of their relaxation times, as illustrated in Figure 108.

Other techniques have also been used for the ^1H imaging of solids, including solid echoes⁹⁵¹ and magic echo phase encoding.⁹⁵² The latter uses pure phase encoding for the two-dimensional imaging, hence it can be extended to obtain chemical shift information during the data acquisition period. Cory et al.⁹⁵³ proposed another method for resolving chemical shifts in solid images obtained by back-projection, which has some advantages over the more commonly used 2D FT method when T_2 values are very short. They tested the

Figure 107 Pulse sequence for ^1H solid state imaging.⁹⁵⁰ Two different pulse sequences can be used during the storage period as illustrated, in order to provide contrast based on relaxation times. (Reproduced by permission of Academic Press)

Figure 108 ^1H solid state image, using the technique of Figure 107, from a 5-mm diameter tube of adamantane surrounded by a 12-mm o.d. neoprene hose inside a 15-mm diameter glass tube: (a) and (b) illustrate the two storage methods described in Figure 107, while (b), (c), and (d) use spin lock storage with different time periods to discriminate between the components based on T_1 and $T_{1\rho}$.⁹⁵⁰ (Reproduced by permission of Academic Press)

ideas with liquid samples but concluded that solids should be amenable to study, and Miller and Garraway used back-projection in their study of one-dimensional ^{13}C imaging of a polyacrylic solid.⁹⁵⁴ They developed a method of 'refocused gradient imaging' to remove inhomogeneous broadening and used proton decoupling to remove ^1H - ^{13}C dipolar broadening.

Maraviglia and co-workers⁹⁵⁵ developed a novel imaging method based on Magic Angle Rotating Frame (MARF)

echoes. They spin-locked the magnetization at the magic angle, then used a 90° , 180° sequence of audiofrequency pulses to carry out a spin echo experiment in a rotating frame that is tilted at the magic angle. The MARF method eliminates dipolar and other bilinear interactions and thus permits images of solids to be obtained by the projection-reconstruction method when magnetic field gradients are formed from B_0 and B_1 .

An interesting imaging method that has been applied to solids as well as liquids with broad lines is STRAy Field Imaging (STRAFI), in which the sample is placed outside a superconducting solenoid where it is subject to a large gradient.^{956,957} A slice is excited by a sequence of selective pulses and the sample is moved, much as in FONAR and related methods. The method is conceptually simple but the probe needed to reorient the sample to obtain three-dimensional images is quite complex. Nevertheless, STRAFI has been applied to image such materials as Plexiglass and a glass fiber reinforced composite.⁹⁵⁸ In addition, the large gradient inherent in this technique has been exploited, for example, by Kinches, Randall, and Zick to eliminate the distortions caused by magnetic susceptibility effects in heterogeneous samples.⁹⁵⁹

MODERN BIOMEDICAL APPLICATIONS OF NMR

As we saw in Section 13, NMR imaging methods had developed into a practical medical diagnostic procedure by the mid-1980s, and during the decade since then MRI has truly become the tail that wags the NMR dog. With thousands of units installed in hospitals and clinics worldwide, the resources expended on medical MRI dwarf those for all other NMR applications. MRI has become the modality of choice for diagnosing innumerable types of pathology, as described in detail elsewhere in this Encyclopedia. In this section we describe a few of the recent trends in instrumentation and techniques and discuss development of aspects of NMR imaging and spectroscopy that are not yet in the mainstream of diagnostic radiology.

Faster, Better, Smaller

The principal thrusts in the enhancement of commercial MRI equipment over the past decade have been to increase the speed of scanning, to improve the quality and versatility of images through refinements in both hardware and software, and to provide magnets that confine the magnetic field and weigh less so as to decrease the costs for MRI facilities.

As we pointed out in Section 13, commercial MRI instruments invariably used a selective slice selection, followed by the 2D spin warp method in which the data matrix needed for the image is built up a line at a time as the phase encoding gradient is incremented, a process that can consume several minutes. It was recognized very early that spin-lattice relaxation restricts the minimum time for repetition of the pulse sequence in a given slice, and during this period other slices can be studied to build up a pseudo-3D image. Multi-slice capability soon became part of the standard MRI software packages, thus precluding still further lengthening of scanning time. Nevertheless, the already long imaging times created

severe motion artifacts from cardiac, respiratory, and peristaltic motions, and precluded any sort of dynamic studies.

Jens Frahm in his article (*Frahm, Jens: Toward Rapid NMR Imaging*) describes in some detail projects at the Max Planck Institute for Biophysical Chemistry to enhance the applicability of MRI. Along with several other methods developed there (about which we shall say more later) came FLASH (*F*ast *L*ow Angle *S*hot), a technique that uses multiple pulses of low angle for excitation rather than the 90° pulse that had conventionally been used in imaging.⁹⁴³ In a sense, this is a logical extension of the optimum flip angle relation first developed by Ernst and Anderson but, as implemented in MRI, FLASH constituted a major advance. As Frahm puts it:

The new concept offered an unrestricted and user-dependent choice of spatial and temporal resolution so that speed may be traded off for resolution and image quality (signal-to-noise). . . . The main potential seems to lie in the fast scan domain where cross-sectional images of conventional quality may be acquired within seconds.

Other approaches were also implemented about the same time. Hennig et al.^{960,961} utilized principles first demonstrated in the Carr–Purcell–Meiboom–Gill spin echo method to develop a pulse sequence that combined rapid acquisition with contrast due to T_2 in a method known as RARE (*R*apid *A*cquisition with *R*elaxation *E*nhancement). RARE has proved to be a very useful method in clinical studies where pathology, such as multiple sclerosis lesions, can best be detected by T_2 contrast.

What about Peter Mansfield's Echo Planar Imaging (EPI) which was designed to scan an entire plane area of interest in a small fraction of a second? As he says in his Encyclopedia article, EPI was in some ways about 15 years ahead of its time. There were enormous obstacles to overcome, and only around 1990 did former Mansfield collaborators develop EPI commercially at Advanced NMR Systems. One of the major steps along the way was the introduction of shielded gradients, as described in Mansfield's historical sketch:

Back at Nottingham in the mid 80s we acquired a superconductive 0.5 T whole body magnet. It was clear to me even before we received the magnet that if EPI were to function correctly within the close confines of the magnet something had to be done to decouple the rapidly switched gradient fields from the metal structures comprising the magnet cryostat. Work started on gradient screening in 1984 and culminated in the concept of active magnetic screening during the course of 1985. Active magnetic screening of gradient coils was quickly taken up by GE and other major manufacturers and now forms part of the standard range of features offered on all imaging machines. The solution of gradient decoupling has had other benefits, especially with regard to magnetic resonance spectroscopy.

With the addition of shielded gradients, EPI has come into practical use as described in the article by Stehling et al.,⁸⁸¹ and, as Mansfield indicated, NMR spectroscopy has benefitted enormously. In Section 11, we noted the advances in high-resolution spectroscopy resulting from pulsed field gradients (which became practical only when the gradients were actively shielded), and we shall encounter further applications to in vivo spectroscopy in the following section.

Active shielding of the *static* magnetic field, as well as the magnetic field gradients, was also an important part of this development by Mansfield and Chapman^{962,963} and related work at GE by Roemer et al.⁹⁶⁴ As 1.5 T magnets became prevalent, siting problems increased since the fringe field can

interfere with computers and other equipment, while large, moving steel objects (e.g., automobiles, elevators) can degrade the homogeneity of the magnetic field. Shielding is clearly the answer and it came in two forms. Passive shielding is obtained by surrounding the magnet with tons of steel and became a standard part of commercial magnets. However, active shielding provided an alternative that did not have the deterrent of a large increase in magnet weight.

Also, during the late 1980s several low-field (0.1–0.3 T) permanent magnet systems were introduced to provide lower cost instruments that could be sited more easily. Moreover, in some designs the magnetic field is configured in such a way as to avoid the 'tunnel' effect of a long superconducting solenoid. Although sensitivity (often translated into resolution) suffers at lower field, there is often a compensating improvement in contrast from the generally larger T_1 range of water in different tissues at lower field. At the other end of the magnetic field range, only a few whole body magnets of field higher than 1.5–2.0 T had come into use by the early 1990s, and those (up to 4.1 T) were located at major medical research centers. Magnets with 3 T or 4 T fields designed solely for studies of the head have been developed, primarily for functional imaging studies of the brain (as discussed in a later section).

During the mid-1990s advances in magnet design permitted the construction of magnets that provide better access to the subject. One design, pioneered by General Electric and illustrated in Figure 109, uses a magnet composed of two parts, with a space in the center for interventional studies. In some ways this is a logical extension of the 'inside-out' magnet used by Jackson et al.⁹⁶⁵ for other purposes, as we discuss in the following section, but the MRI magnet relies on other innovations as well. For example, very linear x , y and z gradients are generated in the central region where there are no coils, and the 0.5-T superconducting magnet relies on a low-temperature refrigeration system instead of cryogenics. Another innovative design introduced by Siemens uses a low-field electromagnet that can be switched on or off rapidly, and provides generous sideways access for physicians and medical technicians. These systems permit MRI to be used as a noninterventional viewing method to guide interventional procedures such as hyperthermia, where NMR can be used to measure localized temperature (by its effect on diffusion, relaxation times, or chemical shifts). Also, the NMR image permits precise localization of catheters and instruments for minimally invasive surgery.

In addition to improved performance from hardware, such as shielded gradients, MRI has benefitted from significant advances in software that permit better data acquisition in gating pulses and in selection of various viewing planes. Moreover, progress in image processing has accorded radiologists and other clinicians enhanced representations of the imaged volume, which is useful in surgical planning especially for neurosurgery. Computer reconstruction of 3D images whose orientation can be manipulated at will and displayed in perspective is beginning to change the conventional use of two-dimensional slices. In addition, advanced concepts such as 'virtual reality' give promise of even better 3D views for an interventional radiologist or surgeon.

In Vivo Spectroscopy Advances

As we saw in Section 12, there were many significant accomplishments in in vivo NMR, ranging from metabolic studies in cells to animals and humans. Prior to the invention of NMR imaging, localization of the volume of interest in animal and human studies had been accomplished largely by use of implanted rf coils (in animals) or surface coils, together with carefully designed 'depth' pulses to define the volume that is excited. In addition, topical NMR (as we saw in Section 13) provided a small homogeneous volume in B_0 for localization. All of these methods were useful but none provided truly successful localization.

With the development of imaging methods, it became clear that combinations of carefully designed pulse sequences and magnetic field gradients could be used to define a volume of interest and permit chemical shift information to be obtained. In 1975, Lauterbur et al.⁹⁶⁶ published a chemical shift imaging (CSI) technique based upon the projection–reconstruction method. Using a composite phantom of tubes containing liquids with different chemical shifts, they demonstrated that one-dimensional spectra corresponding to different spatial

regions could be obtained and used to reconstruct two- or three-dimensional distributions of each compound.

However, it was a long way from this early demonstration of CSI in a phantom to the perfection of practical localization methods that can be applied to the study of low concentrations of metabolites in living animals and humans. During the 1980s many approaches were tried with varying degrees of success, and many methods are currently in use. Some techniques utilize a surface coil, either in the presence of a gradient in the static B_0 field or based on the B_1 gradient inherent in the surface coil design. For example, Bottomley et al.⁹⁶⁷ used a static gradient and surface coil to produce a simple method for *Depth RESolved Surface Spectroscopy* (DRESS) that localizes a disc-shaped volume whose depth can be controlled. On the other hand, the concept of rotating frame zeugmatography,⁸⁶⁷ which relies on a gradient in the rf field, was exploited with a surface coil to obtain a one-dimensional chemical shift image.⁸⁶⁸ Further modifications of this method have been introduced to improve the efficiency with Fourier series windows.^{968–970}

A large number of methods have been developed to use one or more gradients in B_0 , along with suitable pulse sequences, to select a volume of interest (VOI)

without losing chemical shift information. For example, ISIS (*I*mage-*S*electe*D* *I*n *V*ivo *S*pectroscopy), introduced by Ordidge et al.,⁹⁷¹ makes use of addition and subtraction of the responses to eight selective 180° pulses in the presence of three orthogonal static field gradients to select a VOI. Several methods use a stimulated echo sequence with pulsed field gradients. Frahm et al.^{972,973} developed the now widely known STEAM (*S*Timulated *E*cho *A*cquisition *M*ode), while similar approaches were also introduced in VEST (selected *V*olume *E*xcitation using *S*Timulated echoes)⁹⁷⁴ and VOSY (*V*olume *S*elective spectroscopyY).⁹⁷⁵ Other techniques avoid the disadvantages of an echo and store the magnetization from the VOI along the *z* axis while using pulsed gradients to dephase unwanted signal in the *xy* plane, for example VSE (*V*olume *S*elective *E*xcitation),⁹⁷⁶ SPARS (*S*PAtially *R*esolved Spectroscopy),⁹⁷⁷ and SPACE (*S*PAtial *C*hemical *E*ncoded excitation).⁹⁷⁸ A number of other modifications and improvements on each of these techniques together with other novel approaches have appeared over the years. SLIM (*S*pectral *L*ocalization by *I*Maging) uses the anatomical image to improve the efficiency of acquiring spectral information.⁹⁷⁹

The existence of this variety of methods suggests that no 'ideal' technique has appeared. Each method has its advantages and drawbacks for particular types of experiments depending on the nature of the sample and the type of information to be obtained. In general, the availability of good shielded gradients has been one of the major factors in permitting more sophisticated pulse sequences to be applied.

With the availability of useful localization methods, many applications to biomedical problems have appeared. ³¹P NMR continues to provide noninvasive information on biochemistry, pathology, and pharmacology in humans and experimental animals. The use of localization methods permits studies of the sort illustrated in Figure 110, which show the nonuniform distribution of phosphorus compounds across the human head.⁹⁸⁰ ¹⁹F NMR is also very useful with appropriately labeled pharmaceuticals, anesthetics, and other compounds. With the relatively high sensitivity of ¹⁹F, good localization techniques can provide small NMR localization volumes that often improve NMR resolution over that attainable with ¹⁸F positron emission tomography.

As pointed out in Section 12, the clear advantage of *in vivo* ¹H NMR spectroscopy was initially overwhelmed by the dominant signal from water. Although methods discussed in previous sections were helpful in reducing the H₂O signal, real success came from incorporating pulsed gradients and selective excitation developed primarily for imaging with double quantum filtering techniques that originated in 2D NMR.⁸²⁷ With effective means for the suppression of signals from water (and in some instances from lipids, as well), ¹H NMR became an effective means of following biological processes *in vivo*. For example, chemical shift images of a specific compound could be obtained and displayed, as exemplified in Figure 111 which shows the distribution of several substances in the brain of a patient with a high-grade lymphoma.⁹⁸¹ A number of spectral editing and image processing steps are needed to produce such images. ¹³C NMR presents special problems because of low sensitivity. Most of the progress has been made with surface coils both for observation and decoupling, or for indirect observation via ¹H resonance, in some cases with localization accomplished using ¹H NMR

Figure 110 ³¹P NMR spectra at 1.5 T from localized regions in an axial section of a human head, each covering a cross-sectional area of 9 cm². Note decreased signal in the central region corresponding to the ventricles, and a higher creatine phosphate signal near the surface of the head.⁹⁸⁰ (Reproduced by permission of the Radiological Society of North America)

followed by polarization transfer to ¹³C.⁹⁸² More sophisticated 2D methods are also being used. For example, heteronuclear multiple quantum coherence (described in Section 11), with pulsed field gradients to select coherence order, has been employed to follow the metabolism of ¹³C-enriched glucose in the cat brain with ¹H sensitivity but ¹³C spectral dispersion.⁹⁸³

Functional Imaging

Medical diagnostic imaging by NMR developed in the wake of X-ray computed tomography as a technique to study anatomical features, and this continues to be the focus in diagnostic radiology. The potential value of localized NMR spectroscopy in providing diagnostic information from analysis of metabolic processes was recognized in the 1980s but has not yet been widely applied beyond research activities. Meanwhile, various sequences of rf pulses and pulsed magnetic field gradients have been developed to probe a number of dynamic processes in the human body that give insight into pathology. We focus here on three aspects of these so-called *functional imaging* studies: blood flow, diffusion in tissues, and capillary perfusion.⁹⁸⁴

Long before imaging techniques were developed, Jay Singer had begun to investigate blood flow by NMR,⁸⁴⁹ and work along these lines was continued by Bowman and Kudravcev⁹⁸⁵ and by Battocletti and co-workers.⁹⁸⁶ The early work built on experience gained in the measurement of flow in industrial fluids (as we mention in Section 17) and used continuous wave or simple pulse techniques to tag a bolus of blood by saturation or an inversion pulse, and subsequently measure the NMR signal 'downstream' from the site of perturbation. With such methods, arterial and venous blood flow could be observed in limbs.⁹⁸⁷ The development of imaging opened the door to more general applications, but the initial measurements of blood flow also used a time-of-flight method in which the longitudinal magnetization is perturbed.⁹⁸⁸ While simple and relatively free from artifacts, quantification is problematic.

Figure 111 ^1H NMR multislice, multispin echo images of the brain of a patient with a high grade lymphoma. Images of three slices are shown, located as shown at the bottom of the figure. MRI: Anatomical images, showing a lesion in the lower right quadrant. NAA: *N*-acetylaspartate image, with lipid artifacts shown as bright spots. Cho+Cr: Image from choline and creatine. (Cho+Cr)/NAA: Ratio image, showing the tumor clearly in lower right quadrant. Lac, Lip: Image from lactate and lipid.⁹⁸¹ (Courtesy of C. T. W. Moonen)

An alternative is the phase contrast method, in which two successive field gradients, identical but of opposite sign, are applied. If no flow (or other change in position) occurs between the pulsed gradients, the phase increment from the first is exactly canceled by the second; otherwise, cancellation is incomplete and a difference measurement provides an NMR signal only of the moving liquid. An example of an NMR angiogram based on this principle is shown in Figure 112. Because blood vessels do not conveniently conform to a plane, gradients in all three Cartesian directions are required, followed by 3D image reconstruction. Development of NMR angiography for routine clinical use, based on both phase contrast and time-of-flight methods, seems promising.

Molecular diffusion has been measured by NMR for many years, beginning with the Carr–Purcell pulse sequence in 1954¹³⁴ and becoming more feasible after the introduction of pulsed field gradients by Stejskal and Tanner.⁹⁸⁹ The concept is similar to measurement of coherent flow by spin echoes and pulsed gradients, but the theory accounts for diffusion and other *incoherent* motions. In the mid-1980s several groups showed how the method could be combined

with imaging techniques to provide a diffusion-weighted image.^{990,991,992} The methods have been applied in clinical and experimental situations, for example, to visualize the region of the brain affected by a stroke where the diffusion coefficient is drastically reduced.⁹⁹³ Diffusion imaging has also found application in distinguishing between tumors and the surrounding region of edema. Rapid echo planar imaging has been found to be of particular value in measuring diffusion without motion artifacts.⁹⁹⁴

The perfusion of blood through the capillary system in tissues contains some elements of coherent blood flow coupled with incoherent motion, since the direction of capillary flow varies in an almost random manner. Analysis of such ‘intravoxel incoherent motion’ (IVIM) can, in principle, provide measurement of perfusion,^{992,995} but quantitation is difficult.⁹⁹⁶ An alternative method for visualizing such flow relies on the addition of a paramagnetic contrast agent, usually a gadolinium chelate.⁹⁹⁷ The technique consists of injecting a bolus of paramagnetic material, which alters the magnetic susceptibility of the capillary volume as it passes through. The change in susceptibility imposes an additional, local magnetic

Figure 112 Flow imaging of the human head at 1.5 T. Three data sets, each sensitive to flow along one of three mutually orthogonal directions, were combined to produce the image. (Courtesy of C. L. Dumoulin and S. P. Souza, General Electric Co.)

field gradient on the surrounding tissue, and a difference image shows the passage of the bolus even though the ^1H signal from the volume of blood in the capillaries constitutes a small fraction of the signal from the total tissue volume being studied. The method has been used successfully to provide data on blood volume and flow,⁹⁹⁸ and to produce a functional map of the human visual cortex that reflects changes in regional cerebral blood flow on photic stimulation.⁹⁹⁹

Subsequently, Ogawa et al.¹⁰⁰⁰ introduced a valuable modification of this imaging method for studying capillary perfusion by employing hemoglobin in the blood as an endogenous contrast agent. Oxyhemoglobin is diamagnetic, but when oxygen is consumed in metabolism the hemoglobin becomes paramagnetic. This fact has been widely exploited in visualizing regions of the brain in which metabolic activity occurs in response to an external stimulus—a technique given the acronym BOLD (*Blood Oxygenation Level Dependent Contrast*).¹⁰⁰¹ Since the method depends on local magnetic susceptibility change, which affects T_2^* rather than T_2 , better contrast can be obtained by basing the image on a gradient recalled echo that has been shifted to a longer time than found normally.¹⁰⁰²

NMR Microscopy

Lauterbur's first paper on zeugmatography spoke of 'compositions of microscopic objects'. The development of NMR imaging as a microscopic method has received much less attention than the opposite extreme of human whole body imaging, but the techniques have been developed steadily. The two principal problems in this area are sensitivity (since the sample contains relatively few nuclei) and phase errors that result from molecular diffusion (which is important when displacements due to diffusion approach the voxel dimensions). Considerable effort has gone into optimizing parameters so as to produce images with little distortion in the presence of diffusion and of magnetic susceptibility discontinuities in small samples.¹⁰⁰³ Because the sample size for NMR microscopy is comparable with that used for most high-resolution NMR in chemistry,

high-field spectrometers can be employed with suitable accessories that are now available for commercial high-resolution NMR spectrometers. The advantage of using magnetic fields (up to 14 T) that are much higher than used for human imaging restores some of the loss in sensitivity resulting from the small sample size.

Microimaging has been applied to studies of various polymers, polymer composites, and elastomers using the techniques described in Section 15, and a number of applications to structures in plants and in wood have been reported. However, the major uses of NMR microscopy thus far have centered around investigations of structure and function in small experimental animals, such as mice and rats, and in developmental biology.¹⁰⁰³ For example, in 1986, Aguayo et al.¹⁰⁰⁴ used a 400 MHz spectrometer and field gradients of 20 G cm^{-1} to observe images in a single cell. They could distinguish the nucleus and various features in the cytoplasm. The next year, Allan Johnson and co-workers at Duke University showed excellent delineation of anatomical features in a rat brain with a resolution of ca. $100\text{ }\mu\text{m}$,¹⁰⁰⁵ and subsequently this group and others have made many further advances. Recently, Mansfield and co-workers have built a sensitive, inductively coupled rf surface coil into a microscopic slide, where it can provide NMR images and also be used for optical microscopy. In a particularly favorable case, they observed a resolution as small as $4.5\text{ }\mu\text{m}$.¹⁰⁰⁶

NMR microscopy is becoming a rival of optical microscopy in histopathological studies of tissue where 'routine' isotropic resolution of less than $10\text{ }\mu\text{m}$ has been reported.¹⁰⁰⁷ Such results have been obtained with a receiver coil fabricated by Black et al.¹⁰⁰⁸ from a high-temperature superconductor, $\text{YBa}_2\text{Cu}_3\text{O}_7$, which was used to improve the signal-to-noise ratio by a factor of 50—the first reported use of a high-temperature superconductor for an NMR coil.

OTHER APPLICATIONS OF NMR

In addition to its major uses in chemistry, physics, medicine, and a variety of other sciences, NMR has, since its inception, had application in a number of endeavors of industrial or technological importance. In this section we describe the development of some of these applications, many of which are unfamiliar to the majority of people working with the more common manifestations of NMR.

Searching for Oil, Water, and Submarines

We saw in Section 3 that the first NMR product developed by Varian Associates was the free precession magnetometer, an instrument in which the magnetization from a large sample of water is allowed to precess in the Earth's magnetic field. From the measurement of the resonance frequency (in the range of 2 kHz) and the Larmor equation, a precise value of that field can be measured and variations of the field over some region may provide valuable information. For example, a magnetometer towed on a long rope behind a ship, airplane, or helicopter can sense the presence of a large steel object such as a submerged submarine. Also, variations in geological formations cause small but (with NMR) measurable variations

in the Earth's field, which can give information useful in prospecting for oil or water.

In his historical sketch (*Codrington, Robert S.: Comments on NMR Instrument Development*), Bob Codrington points out that he joined the Physics Department at Rutgers University in 1951 to work for Henry Torrey on a project for the Office of Naval Research to investigate novel methods for submarine detection during the Korean War. Among a number of ideas that were investigated, including the use of ESR and cyclotron resonance of electrons, was the concept of an NMR magnetometer. (Russell Varian was one of the principal members of the guiding committee.) This magnetometer was deployed in the region surrounding the Korean peninsula and apparently worked reasonably well. The NMR magnetometer, in a ruggedized underwater version, was also used in 1963 in an attempt to locate a nuclear submarine (*USS Thresher*) that had sunk in more than a mile of water. Although the NMR magnetometer was regarded as successful in its time, the later development of optical detection methods provided much greater sensitivity and eventually superseded the NMR approach.

The NMR magnetometer was employed in a similar manner in geophysics exploration and provided useful information on possible oil-rich regions. However, even more useful information can be obtained from boreholes. In 1960, Brown and Gamson¹⁰⁰⁹ developed a 'nuclear magnetic logger' (NML) which was lowered into a borehole and operated by first using a current in a coil to polarize protons in the soil surrounding the instrument, then using the same coil to measure their precession frequency in the Earth's magnetic field, thus functioning as an NMR magnetometer. The NML could measure (i) the strength of the overall ^1H signal; (ii) the signal from oil only, obtained by injecting a paramagnetic material to reduce T_2 in the water phase and render it unobservable; or (iii) the T_1 value of the sample.

In 1980, Jasper Jackson and his colleagues published a series of papers with the intriguing title 'Remote (Inside-Out) NMR'.¹⁰¹⁰ They used two coaxial coils of opposing polarity to create a magnetic field that has its maximum value and most homogeneous volume outside the coils (see Figure 113). This magnet can be used in a borehole to provide a resonance field at a selected radial distance from the axis of the hole.⁹⁶⁵ More recently, Kleinberg et al., at Schlumberger, designed an improved version based on three permanent magnets that produce a homogeneous magnetic field 2 cm or more inside the earth formation, with a ferrite-filled rf antenna to pick up the NMR signal from free precession in the Earth's field.¹⁰¹¹

With the development of NMR imaging, an additional avenue for obtaining useful information on petroleum became available. For example, Edelstein et al.¹⁰¹² used a 2-T NMR system with gradients up to 18 G cm^{-1} to examine cores removed from bore holes in order to measure porosity, permeability, and oil saturation. Figure 114 shows the discrimination that can be obtained between oil-filled and brine-filled core plugs. Other materials that have been pumped into wells to enhance oil recovery can also be identified.¹⁰¹³ In addition, imaging has been found to be useful to assess the heterogeneity of core plugs before other physical or chemical analyses.¹⁰¹⁴

If NMR can be used to search for oil, it can equally well be used in the search for water. The *hydroscope* is an instrument designed to look for rock strata with a high water content.

Figure 113 Top: Magnet configuration for the production of a toroidal homogeneous region. Bottom: Plots of the static magnetic field, showing the homogeneous region, and rf field strength.⁹⁶⁵ (Reproduced by permission of Academic Press)

The idea of using NMR in this way was suggested initially by Wes Anderson and patented by Varian Associates in 1962,¹⁰¹⁵ but was developed into a practical instrument only recently in Russia. Following a patent in 1988 by Semenov et al.,¹⁰¹⁶ Legchenko, Shushakov, and co-workers constructed what is probably the world's largest surface coil: a wire some 300 m in length placed in a circle on the surface of the earth in the region to be explored. Pulses at approximately 2.75 kHz provide a response as protons are excited in the Earth's magnetic field. From considerations of the pulse characteristics, it is possible to estimate the depth of the plane from which the principal signal originates. On the assumption that water is likely to lie in strata approximately parallel to the surface, the depth of water-bearing rock and the amount of water present can be determined.^{1017,1018}

Measurement of Flow

The first report of NMR in the presence of flowing liquids appeared in 1951 when Suryan, in India, showed that the arrival of a fresh, polarized sample at the rf coil decreased saturation and resulted in a more intense NMR signal.¹⁰¹⁹ He was also able to estimate T_1 from the flow rate and the geometric parameters of the system. By 1959, Bowman

Figure 114 ^1H NMR images of dolomite core plugs containing only oil (longer plug on left) or only brine (shorter plug on right). (a) Water-selective image; (b) oil-selective image; (c) nonselective image.¹⁰¹² (Courtesy of W. A. Edelstein)

and Kudravcev⁹⁸⁵ had begun to explore the use of NMR to measure blood flow. Their experimental studies were limited to the detection of the flow of water or other fluid through a tube surrounded by a detector coil, but their data showed that the NMR signal could be used to measure flow rate. They explored in a preliminary fashion the effects of relaxation and saturation but did not provide any quantitative framework to analyze the flow results. Later, however, they developed

techniques for making 'time-of-flight' measurements of blood flow, the forerunner of some of the NMR angiographic methods discussed in Section 16.

Meanwhile, also in 1959, Singer⁸⁴⁹ rediscovered the effect of flow on saturation in measurements on a mouse tail. Rather than measure T_1 from flow as Suryan had done, Singer showed that a measurement of both the static T_1 value and the 'apparent' T_1 in the presence of flow permitted an estimate of flow, the principal limitation coming from the fact that the signal was also contributed to by nonmoving tissue. In addition to this procedure, Singer proposed an alternative approach, in which an rf transmitter coil could be used to tag a bolus of blood by saturation or inversion of its magnetization prior to measurement downstream by a second rf coil. This method was demonstrated by Morse and Singer only in 1970¹⁰²⁰ with more sensitive apparatus. Interestingly, they utilized two coils of 6-mm diameter placed over median veins in the forearm of human subjects—certainly one of the first applications of surface coils, well before they were introduced into *in vivo* spectroscopy as described in Section 12.

Although the measurement of blood flow was intriguing, most of the early applications of NMR in this area were to flow measurements of fluids of industrial importance where it was important to isolate the measuring device from a corrosive or reactive substance. For example, Singer made successful measurements of the flow of jet fuel. The Badger Meter Company developed methods for measuring various fluids,^{1021,1022} and by 1970 a commercial NMR flowmeter was being manufactured¹⁰²³ with a permanent magnet and a 'tagging' coil preceding the measuring coil. The flowmeter worked well in many applications but was eventually discontinued, primarily because of its relatively high cost.

An interesting use of NMR in flow measurement is a coal flowmeter and analyzer, designed by King et al.¹⁰²⁴ for the on-stream analysis of pneumatically transported powdered coal. From a combination of NMR and electron spin resonance, they could measure not only flow velocity but also moisture, carbon, and ash content.

Moisture Analysis

NMR has long provided a noninvasive method for measuring water in foodstuffs and commercial products, and is being increasingly employed in agricultural and soil sciences. Probably the first such application was reported as early as 1950 by Shaw and Elsken¹⁰²⁵ who studied hydration in foodstuffs. The work was based on the fact that water molecules in many such products are more mobile than the protons in the host products, which are normally crystalline, amorphous, or highly viscous liquids. The proton spectrum, therefore, consists of a relatively sharp signal superimposed on a broad background. During the next few years, Shaw and co-workers examined adsorbed water in meat products and in ingredients such as collagen, gelatin, egg albumin, and glycine. The potential for commercial use was recognized by Bill Rollwitz at the Southwest Research Institute, who discussed design considerations for a practical instrument in 1953¹⁰²⁶ and later described instruments put into service in 1955 that were based on a CW spectrometer and a 1 kG permanent magnet.¹⁰²⁷ The Schlumberger Well Surveying Corporation developed and marketed

Figure 115 Prototype system for the inspection of baggage by NMR.¹⁰⁵⁶ (Courtesy of Southwest Research Institute)

the Model 104 Analyzer, a 30 MHz continuous wave instrument of sufficient resolution to distinguish water and oil peaks. A Schlumberger brochure in 1957 boasted 'Accurate moisture tests IN SECONDS . . . not hours'. This product line was sold to Varian in 1961 and a modified version, the Varian PA-7, was used successfully in the grain industry.

Pulsed NMR methods were used also to measure T_1 and/or T_2 . The Bruker Minispec, a 10 MHz instrument with provision for a 25 mm or 40 mm diameter sample tube, has been widely used for many years for the analysis of water and other materials where two components are present that differ in T_2 . Two measurements at short and long times often serve to measure the total hydrogen and 'mobile' hydrogen. Over 500 of these instruments had been installed by 1979¹⁰²⁸ and the product line in a more advanced form continues to be widely used.

NMR has been employed by numerous workers to study the moisture content in seeds, dairy products, starches, vegetables, and other foodstuffs. For example, the effect of storage on potatoes, garlic, and apples has been investigated, and significant influences of free and bound water on the properties of foods have been reported.¹⁰²⁹ A variation in the T_2 of water in wheat flour with the addition of salt¹⁰³⁰ has been observed, and the moisture content in such diverse foods as margarine, marzipan, chocolate chip cookies, and pulped sugar beets has been studied.¹⁰³¹ Moisture analysis by NMR has been used successfully in other materials of commercial interest, such as lumber, coal, and concrete,¹⁰³² and in soils as described later.

Oil Content in Intact Seeds

Both wideline and high-resolution NMR have been used for the determination of oil content in individual seeds. In 1963, Bauman, Conway, and Watson¹⁰³³ showed that broad-line ^1H

NMR could be used to measure the total oil content in an individual seed and the results used to select the best seeds for plant breeding. This fast and nondestructive method was able to increase the average oil content of corn 2.25-times faster than was possible with traditional selection methods, resulting in gains over five generations that would otherwise have taken 20–30 generations.¹⁰³⁴ Relatively simple instruments of the type described in the previous section (e.g., the Schlumberger Model 104) were generally used in this work.

The early high-resolution ^1H NMR studies were informative as to types of oil and degree of unsaturation, but the limited ^1H chemical shift dispersion combined with relatively broad lines in the heterogeneous environment prevented identification of specific fatty acids. Moreover, some of these methods were destructive. However, in 1974 Schaefer and Stejskal¹⁰³⁵ showed that high-resolution ^{13}C NMR can be used for the nondestructive analysis of the major fatty acids in single, viable soybeans. Thus, not only could total fat content be determined, but particularly desirable or undesirable unsaturated fatty acids could be readily determined before the bean is planted. Later, this approach was extended to peanuts, corn, castor beans, and sunflower seeds.^{1036,1037} With imaging techniques, Lakshminarayana et al.¹⁰³⁸ studied the distribution of oil and water in sunflower and groundnut seeds.

Other Applications to Food Technology

High-resolution NMR in liquids and in solids (with CP MAS methods) has contributed to analytical methodology in the food industry, as it has in many other commercial enterprises. In most instances the NMR methods are conventional techniques used in chemistry laboratories, even if the samples consist of a wide variety of substances such as cocoa butter,¹⁰³⁹ soybeans,¹⁰⁴⁰ sugar in beet juice,¹⁰⁴¹ rice,¹⁰⁴² gossypol and

its analog in cotton flower buds,¹⁰⁴³ and butyrate in butter oil.¹⁰⁴⁴

An interesting and unusual application is described by Gérard and Maryvonne Martin in their historical sketch (*Martin, Gérard J. & Martin, Maryvonne L.: Ode to Ethanol*). They used deuterium NMR to investigate the adulteration of grape must with added sucrose in order to increase the amount of wine produced—an important economic problem, as they discuss. They go on to say:

Since, from the chemist's point of view, wine can be reduced somewhat irreverently to mainly water and ethanol, we decided to investigate ethanol with the following questions in mind: Is deuterium statistically distributed on the different molecular sites—and, if not, does the natural deuterium distribution depend on the botanical origin of the sugar precursor? This was the beginning of an exciting research project. NMR revealed that Nature is in fact a fascinating laboratory where isotopomeric molecules are biosynthesized in perfectly reproducible conditions for a given botanical species grown in a given environment. If the deuterium content in the methyl position of ethanol is arbitrarily given the statistical value 3, the methylene site is characterized by a factor which not only deviates strongly from the statistical value 2 but also significantly differs for ethanol derived from grape (~2.55) and beet (~2.75) for instance. A method based on the NMR investigation of 'labeling without enrichment' was born.

This method, called *Site-specific Natural Isotope Fractionation* (SNIF) NMR, was commercialized in 1987 and used widely in official wine testing laboratories in France.

Proton NMR imaging has made an impact in the study of the composition and structure of various foods and in physiological processes that result in disorders. For example, studies have been reported on ripening and related processes in tomatoes,¹⁰⁴⁵ apples,¹⁰⁴⁶ and pears,¹⁰⁴⁷ water binding in leaf cells,¹⁰⁴⁸ and chilling injury in citrus fruits.¹⁰⁴⁹ Processes that occur in the production and cooking of meat are also being investigated by NMR imaging, often using the same methods employed in studies of living subjects, such as techniques to image water and fat separately.¹⁰⁵⁰

Plant and Soil Sciences

Since 1960, NMR has been used to study complex mixtures of organic matter extracts from soil where the concentrations of individual components are low. From this work emerged generalizations on the relation between aromatic versus aliphatic components as a function of the age of the soil. Later work in this area has focused primarily on investigations of intact soil samples. Sometimes only the surface water in soil needs to be measured and remote sensing spectrometers have been developed for such applications.¹⁰⁵¹ In other instances, CP MAS studies can provide useful information.¹⁰³¹

NMR imaging, too, can be valuable in studying plant roots in soil, but magnetic susceptibility discontinuities in heterogeneous soil, especially when iron is present, cause significant distortions. Kinches et al.¹⁰⁵² have made good use of the large magnetic field gradient produced by stray field imaging (as described in Section 15) to overcome susceptibility effects.

The first images of intact plants in soil with a spectral resolution of about 0.5 mm were reported by Bottomley et al.¹⁰⁵³ in 1986. The images demonstrated water transport in

roots with light stressed foliage, using water doped with a paramagnetic NMR contrast agent. In addition, the basic root structure and pathology as evidenced by a partial decay of hypogeal cotyledons were indicated. Functional NMR imaging is also being applied to plants in order to define transport pathways in relation to cell water balance.¹⁰⁵⁴

Explosives Detection by NMR?

One of the most unusual applications of NMR was to the detection of explosives in packages and in airline baggage. For a number of years, Bill Rollwitz and co-workers at the Southwest Research Institute pursued the development of a practical device to use NMR relaxation times to detect explosives. Much of the work, initially carried out in secret and building on previous military efforts, was presented in only fragmentary form in internal reports and abstracts of talks at meetings. Solid explosives were found to have unusually long T_1 and short T_2 values as compared with other solids and liquids, and techniques were developed to use these parameters as a rapid means of testing for the presence of explosives. The very long T_1 values (around 1 min for some explosives) presented practical problems in carrying out an analysis in a short time, but was overcome by the use of level crossing techniques in which energy is exchanged between ^1H NMR energy levels and ^{14}N NQR levels. Pulse sequences were selected to distinguish the characteristic relaxation pattern of solid explosives from the large background ^1H NMR signal. A prototype device to detect letter bombs was developed and provided reliable detection of 10–50 g of different types of solid explosives.¹⁰⁵⁵ In addition, a prototype instrument with a 600 G magnet (Figure 115) was built and used to test thousands of suitcases and other airline luggage and cargo, some of which contained simulated explosives of various sorts. The results were encouraging in that there was a high probability of detection and a low rate of 'false alarms'.¹⁰⁵⁶ Nevertheless, the NMR method never became operational, primarily because other techniques offering better sensitivity and fewer drawbacks were developed.

RETROSPECTIVE AND PROSPECTIVE

In Section 1 we said that the history of NMR, like all histories, has no real beginning. Some histories have a distinct conclusion, but that of NMR is nowhere in sight. The imminent maturation of NMR techniques and their use in a routine manner has been predicted for at least 25 years. In several of the articles that follow, the authors point out that more senior and presumably wiser scientists had counseled them in the 1960s or 1970s that the 'exciting' period of NMR was over and they should look for greener pastures. Some did, but most continued to bring further innovation to the field. In a review in 1980,¹⁰⁵⁷ Jonas and Gutowsky pointed out the versatility of NMR and referred to it as 'an evergreen'. The range of articles in this Encyclopedia attests to the continuing richness and practical utility of NMR methods.

The Development of NMR—A Retrospective Look

In this history we have tried to trace the principal threads in the origin and evolution of various aspects of NMR. There are

very many aspects that we have been unable to discuss in detail and others that we have not even mentioned. In the spirit that the history of NMR is a continuing subject, we have focused especially in Sections 14 to 16 on some areas of particularly widespread interest at the time this story was written, but as we examine contemporary developments we clearly lack the perspective that comes only with the passage of time.

This Encyclopedia commemorates the 50th anniversary of the independent discoveries by Purcell, Torrey, and Pound and by Bloch, Hansen, and Packard of methods to observe NMR, as we now know it. Bloch and Purcell did not receive the Nobel Prize for the discovery of NMR, for that had been done by Rabi and his colleagues eight years earlier. Rabi's discovery was an important milestone in physics, but had it not been for the seminal work by the Purcell and Bloch groups, NMR would have remained an important tool for obtaining precise values of nuclear magnetic properties. Period! The observation of NMR in bulk materials, not only in molecular beams, opened new vistas. Physicists and chemists in the 1940s used good judgment in capitalizing on the rich arena opened to them. They worked out the theory in increasingly complex detail and found that NMR could provide unprecedented information about molecular motions in solids and liquids. They learned that chemical environment and bonding had major influences on NMR spectra, and they opened up a whole new industry in analytical chemistry.

Later, it became clear that high-power pulse techniques, which had been used largely by physicists for broadband spectra, and the low-power, sequential scanning that was characteristic of the chemical analysis of multiline spectra could be related in a practical way by Fourier transform methods. The FT revolution ushered in a new era marked by great versatility and by the development of new concepts for studies of solids and ultimately for multidimensional NMR, thus making NMR a far more dynamic and innovative technique. The discovery that NMR could produce three-dimensional spatial images resulted in an even bigger industry in magnetic resonance imaging, which provides not only anatomical, but also spectroscopic and functional information in the biomedical field. Now materials science, too, is benefiting from a combination of all these methods.

Our account of these spectacular developments has been quite limited. In the early days it was largely one-dimensional, as one discovery built on its predecessor. But as the field of NMR underwent exponential growth, it has been impossible for us even to mention many of the valuable contributions by thousands of investigators. In the two most widespread areas in which NMR has been applied over the last 50 years—organic chemistry and medicine—the volume of published work is so overwhelming that we could not even scratch the surface in describing the accomplishments. We have tried to convey some sense of the overall threads of innovation as NMR has developed to its present position. To provide a feeling of continuity in a given specialty, we have divided our account into many sections and subsections. It is clear, however, that the flow of ideas and of technology is not compartmentalized. The concurrent developments in many areas and the interchange of concepts and of new methods continues to be a mark of strength as NMR moves to even greater horizons.

Much more detail and a far greater perception of the excitement in carrying out NMR studies are conveyed in the

200 articles that follow. Had space permitted, many more such interesting stories could have been told. We have introduced a number of these articles within the course of our narrative, but we have not been able to mention others of equal significance.

The Future: 'Plus Ça Change, ...'

In a field that has repeatedly demonstrated surprising new developments, we would not be so bold as to predict the future. Certainly some aspects can safely be forecast, e.g., a continuing effort to attain higher magnetic fields, the use of high-temperature superconducting materials as they are developed, and increasing reliance on complex computational facilities and image processing procedures; these points are so obvious, however, that they are not worth discussing. In concluding this narrative we highlight three contemporary developments, not because they will necessarily become major new techniques, but because they have particular relevance to our earlier history.

In Section 1, we described the Stern–Gerlach experiment which played a critical role in establishing the principles of quantum mechanics and, in modified form, provided the early measurements of nuclear magnetic moments. These measurements were conducted with a molecular beam, the deflection of which served as a detector of the spin state. All of the developments in NMR that we have discussed depended on the replacement of this form of detection by nuclear resonance and nuclear induction in the bulk material. However, in 1992, John Sidles¹⁰⁵⁸ proposed an experiment in which a harmonic restoring potential is added to the Stern–Gerlach concept—an approach that he called a 'folded' Stern–Gerlach experiment. In practice such an experiment could be realized by combining the resonance phenomenon and techniques commonly used in atomic force microscopy. He and others calculated that it might be possible with this technique to observe a single nuclear spin, a gain of perhaps 10^{14} over normal NMR sensitivity! Rugar et al.¹⁰⁵⁹ first demonstrated the feasibility of this approach by using it to measure electron magnetic resonance and, in 1994, this group reported the force detection of NMR.¹⁰⁶⁰ Their measurement involved 1.6×10^{13} protons in a sample of ammonium nitrate, a far cry from a single proton, but major gains in sensitivity are believed to be attainable. Moreover, with the large magnetic field gradient used in this experiment, the measurement already provided a one-dimensional NMR image with a spatial resolution of about $2.6 \mu\text{m}$, an order of magnitude better than that obtained by conventional NMR imaging of solids.

A second reminder of the earliest aspects of NMR is given in Dan Weitekamp's historical sketch (*Fiat, Daniel: The International Society of Magnetic Resonance (ISMAR). Landmarks and Highlights*). In 1927, Dennison explained anomalies in the heat capacity of hydrogen by pointing out that the existence of nuclear spin would cause this molecule to exist in two very different forms, *ortho*- and *para*-hydrogen, which normally do not interconvert.⁴ Weitekamp realized that the perfect spin ordering of *para*-hydrogen might be retained in certain reactions when it is added to other molecules to generate magnetically nonequivalent protons, thereby achieving a very low spin temperature and greatly enhanced NMR signal. The experimental demonstration of this phenomenon at Caltech was published¹⁰⁶¹ with the title 'Parahydrogen and Synthesis

Allow Dramatically Enhanced Nuclear Alignment'—leaving it to others to provide the acronym appropriate to the locale of the experiment. The PASADENA experiment as applied to the catalytic hydrogenation of acrylonitrile provided a signal enhancement of 100–200. As Weitekamp points out, this phenomenon was almost certainly observed previously by others in the course of homogeneous hydrogenation, but was either ignored or misinterpreted as arising from chemically induced dynamic nuclear polarization.

Our third example also illustrates a phenomenon that must have been observed but disregarded by many workers over the years. In late 1993, Warren Warren and co-workers published a paper in *Science* with the intriguing title 'Generation of Impossible Cross-Peaks Between Bulk Water and Biomolecules in Solution NMR'.¹⁰⁶² One of the basic tenets of NMR is that rapid, random tumbling of molecules leads to an averaging out of magnetic dipolar interactions and permits the narrow lines characteristic of high-resolution NMR. A second fundamental assumption in NMR theory is that NMR energy levels lie so close that at room temperature the exponential term in a Boltzmann distribution can be replaced by a linear term—the 'high-temperature approximation'. Warren et al. showed that when a magnetic field gradient is applied, dipolar averaging is incomplete and, together with the limitation of the high-temperature approximation, the usual selection rules do not necessarily apply. In a COSY experiment carried out with a magnetic field gradient, they had found and explained multiple quantum coherences between water and a glycoprotein fragment at low concentration. They called the technique COSY Revamped with Asymmetric Z-gradient Echo Detection (CRAZED) 'because, to an experienced NMR spectroscopist, it looks crazed'. The analysis of this phenomenon not only provided guidance on ways to avoid such unwanted cross peaks but also suggested a possible method for measuring molecular interactions at distances of the order of 1 μm or more.

In concluding with these examples of new developments that hark back to some early aspects of NMR, we are surely not asserting that we have come 'full circle'. NMR continues to thrive on innovation and to broaden its scope, apparently without limit. But even in the midst of impressive technology and sophisticated techniques we are sometimes reminded that we are not very far from our roots.

Acknowledgement

The authors are grateful for help and advice received from many colleagues. First, we thank the authors of the historical sketches that follow. We have learned much about the history of NMR from their articles and have drawn frequently on their words in writing the various sections.

Each of the following has read a draft of one or more sections and provided valuable comments and suggestions for additional items to be included: E. Raymond Andrew, Robert S. Balaban, Ad Bax, James Emsley, James Feeney, Ray Freeman, Allen N. Garroway, Robert J. Highet, and Chrit T. W. Moonen. Their efforts have contributed immensely to the scope and authenticity of this account.

In addition, Eiichi Fukushima, Myra Gordon, Harald Günther, Joel B. Miller, Martin Packard, Edward W. Randall, Bernard L. Shapiro, and Robert G. Shulman have provided very helpful information on a number of historical aspects. Finally, Robin K. Harris and David M. Grant, the Editors-in-Chief of this Encyclopedia have given us constant encouragement and furnished a great deal of assistance in many specific instances.

To enhance the readability of this article, we have provided only limited references, often giving examples rather than attempting a more complete coverage. We hope that the literature cited will furnish a guide to the reader who wishes to obtain further information. In addition to information derived from the specific references given, we have made extensive use of the 200-odd historical sketches that follow, as well as numerous books, monographs, special series on NMR, and review articles that contain material of historical interest. The number is so large that we can provide only a partial list here. In particular, we acknowledge the use of books by Andrew,³⁹ Bertini and Luchinat,¹⁰⁶³ Casy,¹⁰⁶⁴ Chen and Hoult,¹⁰⁶⁵ Cohen,¹⁰⁶⁶ Corio,¹⁰⁶⁷ Emsley and Lindon,²²⁶ Emsley, Feeney, and Sutcliffe,¹⁰⁶⁸ Gadian,¹⁰⁶⁹ Harris and Mann,³⁷⁰ Jackman and Sternhell,¹⁷⁶ James,¹⁰⁷⁰ Jardetzky and Roberts,⁶⁰⁹ Lepley and Closs,¹⁰⁷¹ Mansfield and Morris,¹⁰⁷² Pople, Schneider, and Bernstein,⁹³ Ramsey,¹⁰⁷³ and Sievers.¹⁰⁷⁴ Also helpful have been the major serial review publications, including *Adv. Magn. Reson.*, *Annu. Rep. NMR Spectrosc.*, *Prog. NMR Spectrosc.*, *NMR Basic Principles Prog.*, and *Nucl. Magn. Reson. Spec. Period. Rep.* In addition, we have drawn material from a number of individual articles, primarily historical or subject reviews, including those by Andrew,¹⁰⁷⁵ Bax,¹⁰⁷⁶ Binn and Günther,¹⁰⁷⁷ Bolton and Kearns,¹⁰⁷⁸ Chapman,¹⁰⁷⁹ Chmelka and Pines,¹⁰⁸⁰ Clague,¹⁰⁸¹ Cohen,¹⁰⁸² Cory,¹⁰⁸³ Diehl,¹⁰⁸⁴ Diehl and Leipert,¹⁰⁸⁵ Fenske,¹⁰⁸⁶ Freeman,^{271,1087} Fyfe et al.,¹⁰⁸⁸ Griffin,¹⁰⁸⁹ Gutowsky,¹⁰⁹⁰ Jonas and Gutowsky,¹⁰⁵⁷ Kaplan et al.,¹⁰⁹¹ Khetrapal and Lakshminarayana,¹⁰⁹² Kowalsky and Cohn,¹⁰⁹³ Morris,¹⁰⁹⁴ Nelson and Weaver,²⁶⁷ Pound,⁴⁵ Rigden,¹⁰⁹⁵ Seelig,¹⁰⁹⁶ Shoolery,¹⁰⁹⁷ Slichter,¹⁰⁹⁸ Waugh,¹⁰⁹⁹ and van Zijl and Moonen.⁸²⁷

Our sincere thanks to all those whose written work and oral communications have been helpful in preparing this article.

Biographical Sketch

Edwin D. Becker. b 1930. B.S., 1952, University of Rochester, Ph.D., 1955, Chemistry, University of California, Berkeley, USA. National Institutes of Health, 1955–present; Laboratory Chief (1972–80, 1988–); Associate Director for Research Services (1980–88). Concurrent position on Faculty, Georgetown University, 1959–present. Books on NMR. Research interests and publications: hydrogen bonding, molecular structure elucidation, technique development in NMR and other areas of molecular spectroscopy.

Cherie L. Fisk. b 1945. A.B., 1967, Biochemistry, Smith College. Ph.D., 1975, chemistry, Georgetown University. Introduced to NMR by C. F. Hammer and E. D. Becker. Postdoctoral NMR research, Laboratory of Chemical Physics, National Institutes of Health. Joined Office of Research Services, National Institutes of Health in 1984. Professional interests: design and management of research facilities.

C. L. Khetrapal. *b* 1937. M.Sc., 1959, Allahabad, Ph.D., 1965, Bombay. Introduced to NMR by S. S. Dharmatti. Worked at Tata Institute of Fundamental Research, Bombay, 1959–73 in various positions, the last one being Reader; Raman Research Institute, Bangalore, 1973–84, as Associate Professor and Indian Institute of Science, Bangalore, 1984–present, as Professor and Head, Sophisticated Instruments Facility. Nearly 200 publications and several reviews, books and monographs. Research interests include NMR of oriented systems with emphasis on molecular structure and function, developments of novel techniques, and applications of NMR imaging and *in vivo* spectroscopy to problems of agricultural interest.

Torchia Dennis A.: A Fortuitous Transformation

Dennis A. Torchia

National Institutes of Health (NIH), Bethesda, MD, USA

For once, at least, the formidable Professor Breit (my thesis advisor) had to admit that I had a point; theoretical physics would not suffer by my decision to pursue postdoctoral work in biological, as opposed to real, physics. He therefore supported my application to work in Elkan Blout's lab at Harvard Medical School. Although my original intention was to calculate the UV spectra of protein–ligand complexes, I soon found myself doubting that I could calculate anything meaningful, given the complexity of the system, and I therefore decided to do experiments. Fortunately Blout had a talented group who taught me a variety of spectroscopic and wet biochemical techniques. During a luncheon conversation, a colleague suggested that, as a physicist, I should consider using NMR to study biological systems. This struck me as an odd suggestion because, to my knowledge, an NMR spectrometer was a clever device for measuring either γ or B . However, further discussion and reading convinced me to give NMR a try. Charlie Deber had joined Blout's lab at about the same time as I had, and he and Blout were enthusiastic about using NMR to characterize the conformations of peptides that Deber had synthesized. Blout had established a collaboration with Frank Bovey at Bell labs for this purpose, and Bovey offered me a postdoctoral position to carry out this work.

At Bell, I found myself in an extraordinarily well equipped lab. Bovey had a 100 MHz instrument as well as a share of the Varian 220 in Bob Shulman's lab. With these instruments we were able to elucidate the structures of several cyclic and linear peptides in solution. My interest in molecular dynamics was first stimulated by our observations that proline residues were typically mixtures of *cis* and *trans* isomers in dynamic equilibrium. In addition, our coupling constant measurements indicated that the proline ring was highly flexible, contrary to conventional wisdom.

At about this time, I attended my first ENC where several talks convinced me that pulsed FT ^{13}C NMR was the way to study the dynamics of macromolecules. Shortly after the ENC, I went to the National Bureau of Standards to fill a position that had been vacated by Tom Farrar. Tom and his colleagues had built one of the first pulsed FT ^{13}C spectrometers, and I was eager to make ^{13}C relaxation measurements on polypeptides. However, having only had experience with commercial spectrometers, it was painful, but ultimately very useful, to learn how to optimize the performance of a homebuilt instrument. With help from Dave VanderHart, I eventually got going and, working with Jim Lyster, was able to study the segmental mobility of a variety of polymers and polypeptides.

Shortly after arriving at the Bureau, I established a collaboration with Karl Piez of the NIH to study elastin and soluble fragments of collagen. Although elastin is a crosslinked, insoluble protein, it yielded a motionally averaged ^{13}C spectrum consistent with its rubber-like mechanical properties. The work on elastin initiated my interest in solid

state NMR, and when I joined Piez's lab in 1974 it was with the intention of studying intact collagen using techniques developed by Pines and Waugh. With the help of Dave VanderHart and Rolf Tschudin, I assembled a solid state NMR spectrometer in Ted Becker's lab at the NIH. Using this instrument and its higher field successors, my group studied the dynamics of collagen in various types of intact tissues.

In order to devise reasonable models for internal motions in the protein, we also studied the dynamics of labeled crystalline amino acids and peptides synthesized by Paul Young. These compounds showed a surprising amount of rapid molecular motion, and I began working on equations for T_1 anisotropy and powder lineshape for simple jump models in order to interpret our results. This work led to a collaboration with Attila Szabo, who had just come to the NIH, that yielded equations for anisotropic spin relaxation and powder lineshapes for a wide variety of models of molecular reorientation.

Instruments and equations, however, were insufficient to provide useful information about the molecular dynamics of collagen and elastin. We also had to incorporate labeled amino acids into the proteins in order to achieve the sensitivity and specificity needed to obtain interpretable spectra. We did this by injecting solutions of labeled amino acids into young rodents for several weeks, and then, after sacrificing the animals, removing the tissues of interest. While this procedure worked, it was distasteful and expensive.

As an outgrowth of our work on crystalline amino acids, I had become interested in studying the internal dynamics of crystalline proteins. A colleague at NIH suggested I contact John Gerlt, at the University of Maryland, who had an efficient system for expressing recombinant staphylococcal nuclease in *E. coli*. By coincidence, John called me to ask for a small amount of ^{13}C labeled proline. I said 'yes', and made a request of my own. John and his postdocs generously provided us with transformed *E. coli* and the advice needed to make and purify nuclease. Initially we prepared polycrystalline protein samples containing one type of deuterated amino acid, and obtained clear evidence that the side chain of each type of labeled amino acid was mobile.

In order to overcome the problem associated with overlapping powder patterns, we next obtained CP MAS spectra of $^{13}\text{C}/^{15}\text{N}$ labeled samples. These high-resolution spectra enabled us to observe signals corresponding to individual atomic sites in the protein. Furthermore, we observed in nearly every instance that the ^{13}C and ^{15}N chemical shifts in the crystalline state were the same as in solution. Hence if we could assign the solution spectrum, we would be able to assign the crystalline spectra. At 17 kDa, nuclease was, at the time, considerably larger than any protein that had been assigned; however with the ability to label the protein, it seemed reasonable to suppose that it could be assigned using heteronuclear NMR techniques. This initiated work, in collaboration with Ad Bax, on protein dynamics and structure in solution, which has become the primary focus of my research.

When I reflect upon my decision of 25 years ago to give NMR a try, I was most fortunate to have chosen a technique that has become an essential tool in biophysical research, and I am gratified that I have been able to contribute to its development in this area.

Biographical Sketch

Dennis A. Torchia. *b* 1939. B.A., 1961, Physics, University of California, Riverside, Ph.D., 1967, Physics, Yale University. Postdoctoral fellow, Harvard Medical School, with Elkan Blout, 1967–69, Bell Laboratories, with Frank Bovey, 1969–71. Staff member, National

Bureau of Standards, 1971–74; Dental Institute, NIH, 1974–present. Currently, Chief, Protein Biophysics Section, Bone Research Branch. 120 publications. Current research specialty: application of solution state heteronuclear NMR techniques to the study of protein structure and dynamics.

Torrey, Henry C.: Precursive and Early Work on NMR

Henry C. Torrey

Rutgers University, New Brunswick, NJ, USA

Serendipity is defined by Webster as ‘the faculty of finding valuable or agreeable things not sought for’, and the adjective *serendipitous* describes those who have this happy faculty and the discoveries they make with it, but perhaps it can also be used to characterize a new field of endeavor replete with valuable, agreeable, and surprising things waiting to be uncovered whether by accident or design. In this sense the field of nuclear magnetic resonance is *serendipitous par excellence*. The history of this field is full of examples of new, delightful, and surprising developments after one had supposed that its fabulous fecundity must have been finally exhausted. Most of these treasures have been unearthed by informed search or ingenuity, but some by serendipity.

The first observation of NMR by I. I. Rabi and colleagues¹ was anything but serendipitous. They had planned their work carefully and saw what they had expected to see. They interpreted their observations on the basis of a formula for the probability of a spin- $\frac{1}{2}$ flip derived by Rabi² a few months before for the case of a gyrating magnetic field. However a curious thing seems to have happened on the way from reference 2 to 1. In the earlier work, the spin flip probability, P , was not displayed with a ‘resonance denominator’ and the focus was on the asymmetry in its value depending on the direction of rotation of the field, making possible the determination of the sign of the moment; indeed the word *resonance* does not appear anywhere in this paper. In the later work, P was shown with the ‘familiar resonance denominator’ and the emphasis was on the precise measurement of the moment with an oscillating field. In between times Rabi was visited by the Dutch physicist, C. J. Gorter, who had made an unsuccessful attempt³ to observe NMR in a solid, but who realized that Rabi’s setup was ideal for observing NMR if his spatially rotating field were replaced by an oscillating field transverse to a steady field. He urged⁴ Rabi to do that, but felt⁴ that he had not succeeded in convincing him.

But actually Rabi **was** convinced. Gorter’s visit was on a Saturday; on the following Monday modifications were underway⁵ in Rabi’s laboratory to prepare for the famous resonance experiment. According to Rabi⁶ it wasn’t Gorter’s advice, ‘he didn’t tell us anything we didn’t know’, but the possibility of his competition that provided the stimulus. This remark seems a bit disingenuous. It wasn’t like Rabi to be paddling about in backwaters, ‘... I liked what we were doing ... nobody was competing with us ...’, when the tide leading to a Nobel Prize was at the flood. There are other things than competition that can cause the tide to slacken: accidents, ill-health, unexpected and peremptory demands on one’s time and attention, etc. It wasn’t in Rabi’s nature to delay embarkation on a major voyage because he seemed to have all the time in the world. Accepting Rabi’s statement that Gorter didn’t tell him anything new, it seems likely that the major effect of

Gorter’s visit was to waken Rabi to the vital significance of the resonance method and to the realization that he had better get on with it before the tide slackened for whatever reason.

Gorter’s expressed reaction⁴ to the Letter¹ announcing the discovery of NMR was restrained and graceful: ‘I cannot deny that I felt some pride, mixed with the feeling that my contribution was somewhat undervalued though my advice was acknowledged in the Letter.’ A few years later Gorter and Broer,⁷ for reasons still obscure, narrowly missed making the first observation of NMR in bulk matter. No one has ever doubted that Rabi richly deserved the Nobel Prize he was awarded in 1944, but Gorter clearly deserved a noble prize for the good grace and lack of rancor with which he accepted the undervaluation of his contribution to Rabi’s success as well as the near misses in his own quest of NMR and his ‘bad luck’ in other major scientific endeavors.

My own connection with this field began in early 1935 when I was a graduate student in Rabi’s molecular beam laboratory at Columbia. At this time Rabi had conceived of a way to determine the sign of a nuclear moment by a new use of the refocusing technique: a deflecting field A , a refocusing field B , and in between a C field to induce nonadiabatic transitions. It was my privilege to be the first to use this technique in Rabi’s lab and I set to work with enthusiasm to build my apparatus. My thesis problem was to determine the sign of the nuclear moment of potassium (^{39}K). At the weak fields I was using in A and C , the nuclear spin of $\frac{3}{2}$ was closely coupled to the electron spin, but in the strong B field the three states with total angular momentum $F = 1$ all had nearly the same moment, so no change could be noticed due to transitions among them. On the other hand, the transitions for $F = 2$ of $m = 1$ to $m = 2$ or of $m = -1$ to $m = -2$ would change the sign of the moment in the B field, causing a decrease in the refocused intensity. This difference could easily be exploited to find the sign of the nuclear moment.

Everything went beautifully: the first run I took late in 1935 gave me all the data I needed and I was finished, or so I thought. I had succeeded in inducing detectable changes in the orientation of an atomic moment to which a nuclear moment was coupled, so in a sense I had flipped a nuclear spin and detected it, which no one else had done up to then. Unfortunately, one is not awarded a Ph.D. for demonstrating the calisthenics of atomic and nuclear moments. At least one bit of new information had to be added to the world’s knowledge. The sign of the moment of ^{39}K would do and I had that, but soon after my run the highly respected British spectroscopist, D. A. Jackson, published⁸ with H. Kuhn their observation of the hyperfine structure of ^{39}K , including the sign of its nuclear moment, and I appeared to be scooped. My thesis was in ruins and I would have to start over again, or so it seemed at first. But fortune smiled again. I had found the moment to be positive and Jackson, near the limit of resolution of the hfs splitting of ^{39}K , had declared it to be negative. I was sure I was right, but to be completely convincing it was felt that I should make a direct comparison with sodium (^{23}Na) which was known, spectroscopically, to have a positive moment.

My apparatus which had behaved impeccably up to this time seemed to resent being asked to accommodate itself to sodium for which it was not designed. It developed hard-to-find leaks and other forms of recalcitrant behavior. Finally, after several months of coercion it produced an acceptable beam, but I then found that my A field was insufficiently long to resolve

the hyperfine magnetic states of sodium to the extent needed to obtain a completely unambiguous result. In the meantime Kellogg, Rabi, and Zacharias⁹ had found the sign of the proton moment by a similar method. They had started after I did and had no results when I took my first run, but the delay caused by my work on sodium prevented me from being the first to publish in this field. After all these frustrations I was able to use another apparatus which S. Millman had constructed for a different purpose. This had a sufficiently long A field and with the cooperation of Millman and J. R. Zacharias it was modified to my present purpose. With it, I found the signs of ³⁹K and ²³Na to be the same and positive, confirming my previous result.¹⁰

My first post-Ph.D. job was at Penn State, where I arrived about the same time that Gorter made his famous visit to Columbia. I was fascinated by Rabi's stunning development of NMR and wanted to get into the field, but could not hope to compete experimentally. My first foray into magnetic resonance was some theoretical work¹¹ on radiofrequency spectroscopy with the atomic beam method of Rabi.

One virtue of the Rabi method is its theoretical simplicity. However complicated the atomic or molecular system, you are usually dealing with what may be taken as a two-level system: one level is the refocused state you are observing, the other the state to which you are inducing transitions. I first showed that the Schrödinger equation for a general two-level system perturbed by a sinusoidal potential has, to a close approximation, a solution formally identical to Rabi's solution for a spin- $\frac{1}{2}$ in a gyrating field. The transition probability is a function of the time that must be averaged over the velocity distribution in a molecular beam and this I did. Finally, I derived the matrix elements for the Zeeman components of the hyperfine-split ground states of the alkali atoms in a magnetic field, applying these results to the shapes and intensities of the resonances found^{12,13} in Rabi's laboratory.

World War II put a virtual stop to all nonwar-related scientific research. I was called to the Radiation Laboratory at MIT, where I worked on the development of crystal rectifiers which were used in the detection of microwave radar signals. Next door to me at the Rad Lab was Robert V. Pound, head of crystal mixers, who later became my office mate and my collaborator with Edward M. Purcell in the first observation¹⁴ of NMR in bulk matter. Many years later, Purcell and I had a conversation in which we agreed that because of his prodigious memory Pound was best qualified to write the history of this work. The accompanying article by Pound (*Pound, Robert V.: Early Days in NMR*) includes a condensation of this history which he drafted in consultation with Purcell and myself.

Since Pound is the designated 'historiographer' of this work, I will refrain from repeating any of its history here except for a few minor comments on Pound's statements. He gives an account of the lunch where Purcell asked my opinion as to the feasibility of detecting the resonant absorption of radiofrequency power by nuclear spins in bulk matter. I do recall saying something about talk at Columbia being pessimistic on this question, but I now have no memory of such talk and believe that I was perhaps thinking subliminally of Rabi's Letter,¹ announcing his first observation of NMR, in which he refers in a footnote to Gorter's failure³ to observe NMR in a solid. Incidentally, I seem to recall that there were two other people present at this luncheon, but don't remember now who they were.

Pound mentions my estimate from Waller's work that the nuclear spin relaxation time might be as short as 'several hours'. I have not saved these calculations, but I distinctly recall that my estimate was about an hour, a shaky estimate because Waller's work was for a crystal and did not apply well to paraffin. I was well aware that relaxation through lattice vibrations would only give an upper limit to the relaxation time and hoped that there would be other more efficient processes which turned out to be the case: the actual relaxation time for paraffin is in fact only about 10^{-2} s.

During the course of our work, Rabi called me into his office one day and quizzed me about it. He asked me how we expected to observe a resonance in view of the obscuring effects of local magnetic fields that would be present in a solid. I gave my opinion that any such fields would do no more than broaden the resonance by a few gauss. He was not convinced by my arguments and was very skeptical about our chances for success.

The announcement¹⁵ of the discovery of 'nuclear induction' by Bloch, Hansen, and Packard a month after our report caused some initial confusion. It was clear that the two effects were closely related, but just how was not fully understood at first. A few weeks later Felix Bloch visited MIT, conferred with us and gave a talk on his work with Hansen and Packard, clearing up the remaining confusion on the relationship between our work and 'nuclear induction'. Summaries of his talk were distributed widely and excited considerable interest among some of the physicists still remaining at the Rad Lab, most of whom were engaged in finishing their contributions to the Rad Lab series of books. Before leaving MIT, I had talks with a number of people, including S. A. Goudsmit, who was much taken with the Bloch equations for the components of the nuclear magnetization in the rotating frame. He urged me to make a careful study of them and to examine and test them experimentally. I decided to follow his advice at my postwar job at Rutgers University where I joined the Physics Faculty in June 1946.

Before the war Rutgers had little going in the way of scientific research apart from an active agricultural experiment station. However, Rutgers had been designated the State University of New Jersey and was facing the task of educating hordes of returning war veterans. I was one of six physicists recruited in 1946 from the MIT Radiation Laboratory in a program to build up instruction and research in physics. Included in this program was a substantial grant to acquire research equipment, among which was a large electromagnet, perhaps the first ever to be designed specifically for NMR use. This magnet, built to our specifications by the General Electric Co., had a 3.5 in. adjustable gap separating 18-in. diameter pole faces. It was energized by a motor generator with the output current stabilized electronically by circuits designed and built by H. S. Somers, Jr. and P. R. Weiss of the Rad Lab contingent and was capable of providing more than 1.2 T. It gave excellent service for some 40 years.

Early in the summer of 1946 I gave a seminar at Rutgers on NMR, the notes for which were written up and distributed to the Rutgers staff; copies were sent to other laboratories including Harvard and Columbia. In these talks, I applied (I believe for the first time) to the case of magnetic resonance the well-known kinematic formula for the motion of a vector in a rotating frame in terms of its motion in the original frame. This procedure, soon commonplace, gives a very *anschaulich*

picture of the motion of the magnetization vector if the rotating frame is the one in which the effective rotating component of the magnetic field is fixed. It is seen to be a uniform precession about a fixed vector in the rotating frame with rectangular components: γH_1 and $\gamma H_0 - \omega$ at an angular frequency equal to the magnitude of this vector. From the point of view of the laboratory frame, the motion appears as a nodding or nutation of the magnetization vector with the above frequency.

The Bloch equations¹⁶ for the rate of change of the components of the nuclear magnetization in the rotating frame include, besides the magnetic field torque, the interactions of the spins with the lattice and with themselves. These interactions are incorporated simplistically in the equations as linear relaxation terms with different time constants, T_1 for longitudinal decay and T_2 for transverse decay. The steady state is given by putting the time derivatives equal to zero and gives simple Lorentz-shaped resonances with saturation terms in the denominators.¹⁴

It was clear to me that nutational motions of the nuclear magnetization as predicted above could be observed as transients following the application of pulses of radiofrequency magnetic fields. These transients would be damped by the relaxation terms above and the nutational frequency would also be affected by them. The Bloch equations are simple linear differential equations of the third order and their solutions can be written down in terms of the roots of a cubic algebraic equation. The general result is mathematically messy, but is greatly simplified in three special cases which cover most situations of interest: (a) exact resonance; (b) $T_1 = T_2$; or (c) T_2 long compared with the nutational period. I worked out these solutions and compared them to observations in liquids such as glycerine and distilled water.¹⁷ This was the first application of rf pulses in NMR.

My motivation in using pulses was to observe the nuclear signal during the rf pulse; if I had looked for the free decay of the nuclear signal after a pulse I might also have seen the amazing phenomenon of *spin echoes*, observed soon after my work by E. L. Hahn¹⁸ in the outstanding example of serendipity in the history of this serendipitous subject. Even if I had seen the echoes I might not have divined their nature. Hahn, at the time just a graduate student with no knowledgeable person then at the University of Illinois to advise him, deserves a tremendous amount of credit for finding the right explanation of the phenomenon which he first regarded as a nuisance. It was the excitement generated by spin echoes that was responsible for a surge of interest in pulse techniques in NMR leading to many major developments in the field, many of these the handiwork of Hahn and his collaborators.

My work with pulses continued with an examination of the effects of a long train of pulses, each with the same duration and with equal intervals between pulses. If a pulse starts with the magnetization oriented along the steady field and endures for an integral number of nutational periods, the magnetization will be left with the same orientation and some attenuation due to the relaxation processes, but will grow during the succeeding off-time. After sufficient time a steady state results in which the nuclear signal is large if a pulse duration is short compared with the relaxation times even for fairly closely spaced pulses, but if the condition on the nutational period is not exactly satisfied the magnetization will make increasing angles with the field on succeeding pulses and the signal

will be small. This phenomenon, which I called nutational resonance, was used¹⁹ as a means of measuring long T_2 values in the case of motionally narrowed NMR lines. About this time a considerable boost to NMR at Rutgers was made by the addition of H.Y. Carr, whose Harvard thesis under Purcell incorporated many ingenious refinements and extensions of spin echo techniques.

The Bloch equations, in spite of their phenomenological nature, give a surprisingly accurate account of lines sharply narrowed by motion or exchange. Questions have arisen as to their accuracy in weak fields where a distinction might be noticed between relaxation with respect to the steady field or with respect to the instantaneous field. Testing this question in NMR is difficult because of the weakness of signals, but is easy in ESR (electron spin resonance) where the signal is relatively strong. Using free radicals with sharply exchange-narrowed ESR lines, it was found²⁰ that the ordinary Bloch equations gave results strongly deviating from experiment for the absorption of radiation as a function of magnetic field passing through zero, but these data agreed well with the predictions of Bloch equations modified so that relaxation was assumed to take place with respect to the instantaneous rather than the steady field.

A final modification of the Bloch equations was made²¹ to provide for the case of diffusion of magnetization by including diffusion terms. I illustrated the use of these terms by applying the equations to spin echo effects. Just after submitting this article to the *Physical Review*, I read a paper on this subject at a meeting of the American Physical Society in New Haven, CT. In the audience was Lars Onsager, the famous Yale physical chemist, who in the question period pointed out that the equations as I had presented them would not lead in general to thermal equilibrium. I had to agree with him and after the talk I thought of a further modification that would overcome his objection. Seeking him out, I presented this idea to him and he agreed that it would do the trick. I hastily recalled the paper from the *Physical Review* and made the change required. Unfortunately, the footnote in which I acknowledged Onsager's help made it sound as though he had suggested the specific change I made and some people have so interpreted it, giving it a cachet which it doesn't deserve. As I pointed out in the paper, the change, which amounted to a drift current caused by forces on magnetic moments by field inhomogeneity, was not experimentally significant in NMR, although it later turned out to be so in ferromagnetic resonance.

All the modifications of the Bloch equations I have suggested, both for weak fields as well as for diffusion, are incorporated in equation (4) of Ref. 21. Although my researches at Rutgers on NMR extended in other directions, the scope of this article is restricted to my early work on the Bloch equations.

On the evening of December 15, 1945, after our first observation of NMR in a solid, Purcell, Pound, and I were sure that we had started something that would engage the interest and activity of many people, and would have many applications beyond what we could then imagine. But if we had been given a crystal ball to see the state of the art as it is today, we would have been astonished at its extent and variety, and above all its usefulness. A short time ago, Ed Purcell remarked to me that we could be thankful that the uses of NMR were all beneficial. Still imbued with a Cold War mentality, I replied somewhat cynically that some destructive use unknown to us

had probably been found if not for it, then by it. Now I have cast aside such unworthy thoughts and rejoice with Ed and Bob at all the many happy issues of our old enterprise.

Veeman, Wiebren S.: Personal Reflections on Solid State NMR in the Early Days

Wiebren S. Veeman

Gerhard-Mercator-Universität Duisburg, Duisburg, Germany

After I completed my Ph.D. in Leiden in 1972, I had the opportunity of a postdoctoral stay at the IBM Research Laboratory in San Jose (CA) with Dr. C. S. (Nino) Yannoni. It was from him that I heard for the first time of experiments to obtain 'high'-resolution NMR spectra of solid samples. I learned that, at that time, there were three techniques to obtain high-resolution solid state spectra: a technique invented by Mansfield and Grannell,¹ the now well-known proton-enhanced ¹³C NMR technique of Pines, Gibby, and Waugh,² and a technique from Bleich and Redfield, of which a full account was published much later.³ Yannoni was working with the latter technique, with which he had been able to obtain the ¹³C chemical shift anisotropy of solid benzene⁴ and the ¹⁹F spectrum of 1,1,1-trifluorotrichloroethane in an adamantane host by fluorine–hydrogen intermolecular double resonance.⁵

I was supposed to carry out further work on the development of matrix isolation NMR, whereby the structure of a reactive species in an inert fluorinated matrix could be determined with high-resolution solid state NMR. In contrast to the proton-enhanced method, the Bleich–Redfield technique was basically a continuous wave experiment in which an abundant spin signal was observed. The experiment was switched between a detection period, during which the signal of abundant spins *I* was observed off-resonance in a time-shared way, and a cross-relaxation period, in which on resonance a Hartmann–Hahn⁶ contact was made between spins *I* and a second spin species *S*. By selectively irradiating the *S* spins, the *S* spin spectrum could be plotted out via the intensity

changes of the *I* spin signal. At that time the experimental difficulty of the Bleich–Redfield technique was tremendous. Three rf irradiation frequencies were needed, adiabatically switched on and off, and the experiment was a constant fight against stability and noise problems. Although we knew, for instance, about the magic angle spinning technique,^{7,8} and we talked about the possibility of combining it with the double resonance technique, we did not believe that a combination would be experimentally feasible.

To conclude, I must say that we lost the fight against noise and instability, and after I returned to the Netherlands both of us started to work with the proton-enhanced ¹³C technique which is much less sensitive to instrumental instabilities. I nevertheless think that I would have learned less of solid state NMR and NMR equipment if the proposed experiment had been successful from the beginning.

Vega, Alexander J.: Beginnings, Vaughan, and Solid State NMR

Alexander J. Vega

Dupont, Wilmington, DE, USA

I was born in 1938 in the small town of Ouderkerk in the vicinity of Amsterdam. During the Nazi occupation of the Netherlands, I was hidden by a Christian family in Arnhem and later in the north of the country.

I received my undergraduate degree from the University of Amsterdam with a combined chemistry/physics major. There was a lot of math to catch up on when I decided to continue in physics. Still inspired by my math teacher, S. A. Colthoff from the Amsterdam Jewish High School, I went about this thoroughly. It took me quite a while, as I was a slow student.

I had my first encounter with magnetic resonance when, as part of a required tour of various research labs, I spent two months with John Henning and Cees de Waard who were doing ESR at the Physics Laboratory (the 'Nat Lab') of the University of Amsterdam. I immediately became intrigued by this technique which seemed so fundamental in its physical methods and powerful in its analytical power. I continued my Master's work with John and Cees, who introduced me to NQR and showed me how to build an oscillator. Later the magnetic resonance group was led by Harold de Wijn, a superb inspiring physicist. There I learned to do science and to recognize the essence of physical phenomena without being sidetracked by formalism. At that time I married Ankie Boas who was a math student in Amsterdam.

In the summer of 1967 we made a trip to Israel to look for a place to do my Ph.D. work. I visited the magnetic resonance labs of several academic institutions. At the Weizmann Institute in Rehovot I was received by Daniel Fiat. He showed me Abragam's book and asked if I could read it. Back in Holland we were familiar with Slichter's book while Abragam was considered to be at a more difficult level. Luckily, I had just managed to master a few of its passages, so I could answer 'yes' to the question. A quickly arranged oral exam by Shlomo Alexander got me accepted to the chemistry Ph.D. program before the end of our vacation. At the Weizmann Institute, Danny and his students were enthusiastically investigating the solvation chemistry of paramagnetic ions in aqueous solutions. They educated me in the chemical approach to NMR. However, in view of my earlier transition to physics, which I considered to be superior, I somewhat resented having to practice chemistry myself. Danny did his best to comply with this foolish notion and suggested that I work on crystal water in paramagnetic solids. In all, Fiat has been quite supportive of me. I remember his excitement when he returned from the conference where John Waugh announced the WAHUA experiment. Danny understood that this technique was going to have a great future. He arranged for me to spend the summer of 1969 at MIT, the year that Ulrich Haeberlen left, Michael Mehring came in, and Alex Pines was a student there. That visit helped me a lot. I was amazed by the innovative thinking in the Waugh group.

Back at the Weizmann Institute, I eventually became deeply involved in solution state NMR. It started with a problem posed to me by Jacques Reuben, Fiat's first doctoral student, who was instrumental in the development of the use of rare-earth shift reagents. The problem had to do with the pseudocontact shift of nuclei in the vicinity of paramagnetic ions in solution and an anomaly that Jacques had identified in the theory developed by McConnell and Robertson. I struggled for a long time to find a suitable formalism to tackle this problem, until I got hold of Jack Freed's first manuscript dealing with the stochastic Liouville equation. Jack just happened to be working on this paper during a sabbatical visit with Zeev Luz at the Weizmann Institute. I now had a way to describe the spin states of molecules with randomly changing orientation.

It finally dawned on me that the pseudocontact shift anomaly arose from an often made but mistaken application of the motional-narrowing concept to the equilibrium state of spins in fast motion: it is wrong to assume that the equilibrium distribution of spin states (in this case those of the unpaired electrons) is averaged by fast molecular motion. I defended this contention in heated discussions with people like Shlomo Alexander at the Hebrew University and Danny Fiat. In fact, the main thrust of my Ph.D. work was a systematic justification of this point. It was amusing to see the debate on motional averaging of the equilibrium spin state, in a slightly different context, resurface in the NMR literature as recently as last year.

My closest associate during my years at Weizmann was Avraham Achlama, a Fiat student who did fundamental work on the contact shift. A particularly enriching experience was the weekly seminar, originally together with Zeev Luz's group, where Abragam's book was thoroughly read and discussed.

In 1974 I was in Nottingham at the AMPERE Congress. There I met Bob Vaughan. I stepped up to him and asked if I could be a postdoc with him. He came to listen to my talk and then said that I could come. I spent two years at Caltech, from 1975 to 1977. The atmosphere there was inspiring. Bob was always talking about new opportunities for innovative developments of NMR, but never as a sterile science. New experiments should be developed with a realistic chemical purpose in mind. This was new to me. At that time I did not know of anyone who was applying modern solid state NMR with that level of dedication to practical problems. I was asked to collaborate with Mike Stoll on the development of the pulse method which is now known as the separate local field technique (SLF). The idea was to use the axis frame of the chemical shift tensor to determine experimentally the directions of internuclear vectors. It was all part of Bob's vision. He vividly pictured molecules sitting on surfaces, undergoing reactions, their structures figured out by NMR.

Working with Mike Stoll and sharing a room with him was a rewarding experience. With him, I marveled at the wonder and beauty of physics and at all things physical and spiritual, for that matter. I was there when Mike stumbled on the pulse sequence $xyxyxy$ and calculated that its only effect on the spins was to phase shift their wavefunctions by 180° . He immediately recognized this as a manifestation of the spinor property of half-integer spins and realized that the only way of observing it would be by interference with the wavefunction of a second spin. This led to the 'spinor experiment' which I only began to believe after I worked it out in density matrix

formalism. In that form, it turned out to be nothing more than another example of multiple quantum NMR, the new family of experiments just being initiated by my brother Shimon and by Alex Pines in Berkeley. As a byproduct, we discovered the virtues of multiple quantum relaxation, albeit without calling it such. Soon after completion of his Ph.D., Mike Stoll left spectroscopy to become a radiologist.

Since 1977 I have been at DuPont CR&D, attempting to follow Vaughan's example by trying to perform interesting NMR in the service of the analytical needs of the company. At DuPont, I had the good fortune to collaborate with several outstanding NMR spectroscopists, including Alan English, with whom I worked on ^{19}F multiple pulse NMR of molecular motions in Teflon; Richard Eckman, now at Exxon Chemicals, on deuterium NMR of adsorbed molecules; Zeev Luz, on zeolite characterization and deuterium spin dynamics and relaxation; and Clare Grey, now at Stony Brook, on the

TRAPDOR double resonance experiment with quadrupolar nuclei. Over the years, my brother Shimon and I have met on numerous occasions, during family visits or while sharing rooms at conferences. Although we have mutual interests in many aspects of life, our conversations inevitably drift towards magnetic resonance, the topic that evidently continues to intrigue both of us a great deal.

Research interests: solid state NMR for applications in materials research.

Vega, Shimon: From Zero Field via Double Quantum to Dressed States

Shimon Vega

Weizmann Institute of Science, Rehovot, Israel

I was born in Ouderkerk, a village about 10 kilometers outside Amsterdam, in 1943, in the middle of World War II. At that time my parents were still at home; my brother and sister, however, were already hiding with good families. When I was six weeks old, the Dutch Underground Movement brought me to a wonderful lady and her daughter, who took good care of me until the end of the war.

Like Lex, I went to high school in Amsterdam and studied physics and mathematics at the Gemeente Universiteit of Amsterdam. For my doctorandus studies, I joined the solid state physics group of Dr. A. R. Miedema who was investigating low-dimensional ferro- and antiferromagnetic materials. Evert Maarschall, a member of this group, was dealing with ^{19}F NMR of K_2NiF_6 , and I assisted him in measuring fluorine line-shifts and -widths. Evert loved quantum mechanics and so he taught me the quantum description of NMR with the help of ‘The Feynman Lectures on Physics’.

After my wife and I decided to look for a Ph.D. fellowship in Israel, I went there to look for a supervisor who would be ready to take me as a student. During my visit I met Zeev Luz in the hallway of the Physics Department of the Weizmann Institute. He told me that he had just taken charge of the ^{14}N pure NQR spectrometer that belonged to the group of Shlomo Alexander. He invited me to join his group and to start a Ph.D. project on pulsed ^{14}N NQR. I agreed and at the end of 1969 we arrived in Israel. The group of Luz was very active and stimulating. For example, under his leadership his students, together with students of Daniel Fiat, Mordechai Shporer, and David Zamir, held evening seminars, where we read Abragam ‘without skipping a word’.

To interpret my experimental results we had to extend some of the basic theoretical descriptions of NQR on $I = 1$ spins. As a result, and with the steady encouragement and guidance of Zeev Luz, I published a paper on second and fourth moments of the spectral lines of $I = 1$ spins and a paper, introducing a set of fictitious spin- $\frac{1}{2}$ operators, that simplified the density matrix description of zero-field NQR on these spins. In these spin systems the three possible transitions are all ‘allowed’ and all their coherences can be observed.

Toward the end of my Ph.D. studies, Alex Pines visited the Weizmann Institute and told us about his cross polarization experiments. We were very impressed and I asked if I could become one of his first postdocs. He agreed and in the summer of 1974 I joined his group in Berkeley. He suggested that I work on CIDNP and try to measure the isotope enrichment of molecules that undergo biradical cage recombinations. I was not a very good chemist and not successful. At that time Tom Shattuck was working on ^2H NMR experiments and he observed some unexpected experimental results. I joined his efforts to understand his data and tried to help by describing

his results in terms of the fictitious spin- $\frac{1}{2}$ operator formalism. After some time we understood the evolution of the coherences of $I = 1$ spins in high fields somewhat better and we started talking about double quantum coherence. I did not have many problems with the ‘detection’ of the double quantum coherence because I was used to the fact that you could observe *all* transitions of $I = 1$ spins.

At a particular point we came upon the condition for double quantum decoupling of deuterium from protons. Alex looked at the condition on the blackboard and immediately explained to me that in the near future double and multiple quantum spectroscopy was going to become a very important aspect of NMR. I was very impressed. Alex was way ahead of me. Of course, we were aware of the work of Meiboom, Hashi, and Ernst and their co-workers in the field of multiple quantum NMR. I should also mention the frequent visits of Erwin Hahn to Alex’s laboratory and our exciting discussions with him about his work with Brewe and our work. Alex, Tom, and I worked hard and developed the various double quantum experiments: cross polarization, decoupling, coherence excitation, and detection.

Alex, together with his students and postdocs, continued to develop the fascinating aspects of multiple quantum NMR. I was offered a position at the Weizmann Institute. In 1976 I returned to Israel, published my paper on fictitious spin- $\frac{1}{2}$ operators at about the same time that Wokaun and Ernst did, and set up my first homebuilt 90 MHz spectrometer with the help of Yuval Zur. Yuval Zur and Ya’akov Naor, my first graduate students, studied double and triple quantum cross polarization and double and triple frequency excitation schemes of spins with $I = 1$ and $I = \frac{3}{2}$.

Ya’akov was the first in our group who tried to describe our multiquantum results in terms of Shirley’s Floquet formalism. It took us quite some time before we really understood what the Floquet theory could do for us in NMR. However, eventually, with Yuval and Malcolm Levitt, at that time a postdoc at the Weizmann Institute, we published our first Floquet paper, describing ‘ N -proton’ pulse excitations of single $I = \frac{1}{2}$ spins. Later Eric Krauss continued this work and we became Floquet fans.

I achieved tenure in 1980 and two years later I joined the group of Bob Griffin at the National Magnet Laboratory for one year. Bob taught me all about MAS NMR and I participated in their exciting research of multipulse experiments. We made extensive use of the vector picture, describing the trajectories of the magnetization vectors of rotating $I = \frac{1}{2}$ spins, and again applied the Floquet approach to explain the rotor frequency lines in multiple pulse MAS NMR spectra. Back in Rehovot, the Floquet theory was extended and we started calculating dynamic MAS spectra described the rotational resonance (R^2) phenomena in terms of a degeneracy of Floquet states and searched for selective excitation schemes.

New M.Sc. and Ph.D. students, postdocs, and visiting scientists kept joining the group during the years. We studied three-photon pulses and pulse shaping with Gadi Goelman, David Zax, Ed Sternin, and Dov Abramovitch; magic angle spinning with Asher Schmidt, Lucio Frydman, and Ofer Weintraub; zeolites with Irina Kustanovich, Zeev Luz, and Hans-Martin Vieth; also inclusion compounds with Irina and with Inka Allen and Eduardo Zaborowski; and semiconductors with David Zax, Hans-Martin Vieth, Michal Gavish, Aviva Farag and David Zamir. Of course, the inclusion compound

and zeolite projects were only possible with the help of Herbert Zimmerman.

My interest in MAS NMR continued and in 1990 I went for a sabbatical to St. Louis to join Jake Schaefer. His solid state NMR group was continuing its novel and pioneering work and, as a result of Bob McKay's expertise, they had NMR probes that allowed very unique multispin experiments. Jake's group was applying the REDOR technique for distance measurements between heteronuclear atoms. Working with them made me aware of some limitations of this method and together with Andrew Hing we introduced and developed the TEDOR experiments for heteronuclear spin pairs. Before and during that time I was looking for a pulse method, in addition to the existing DRAMA and R^2 experiments, that would extend the homonuclear distance measurements in rotating samples. The Floquet formalism helped me to realize that a simple set of synchronously applied 180° pulses does the job. Based on this idea, the first results of the SEDRA experiments were published together with Terry Gullion, the RFDR and BDR experiments were introduced by the group of Bob Griffin, and the $\Delta S/S$ SEDRA distance measurements were performed.

Back in Rehovot we generalized the Floquet theory, showing the analogy between the normal spin density matrix and the Floquet density matrix and demonstrating the use of effective Hamiltonians in MAS NMR. Today, in addition to most of the research activities mentioned above, we are still exploiting Floquet theory to describe periodically time-dependent NMR experiments, in particular dynamic MAS ^2H NMR and spin lock and CPMAS experiments involving $I = \frac{1}{2}$, $I = 1$, and $I = \frac{3}{2}$ spins with large interactions.

Vold, Robert L.: Reflections

Robert L. Vold

College of William and Mary, Williamsburg, VA, USA

I have been fortunate to observe and participate in the development of nuclear magnetic resonance since the early 1960s. In this article, I will summarize some high points of this continuing journey. These recollections are necessarily personal, and subject to the usual sources of systematic error.

My first exposure to NMR came in 1962, as an undergraduate at the University of California, Berkeley. Professor R. E. Connick was in charge of the advanced inorganic chemistry laboratory, and he gave me and my lab partner some xenon trioxide to characterize as a term project. After I discovered that XeO_3 explodes spontaneously on contact with weighing paper, Prof. Connick informed me that I had used up the world's supply and suggested I find a different project. This involved measuring proton chemical shifts in water/acetone mixtures, with the aim of interpreting the concentration dependence in terms of hydrogen bonding. I was delighted to see, just as described in 'the bible',¹ that at low water concentration the water peak actually appeared at higher field than the methyl protons of acetone. These experiments were done on the latest and snazziest spectrometer, a Varian A-60. This machine was so stable that it wasn't even necessary to calibrate the chemical shifts with an audio sideband generator! I was hooked. I knew I wanted to do graduate work in NMR, and I applied to the University of Illinois because Prof. Gutowsky was there and he had the longest citation list in Pople, Schneider, and Bernstein.

The University of Illinois was a great place for graduate work: there were no scenic distractions for 500 miles in any direction. While standing in registration lines in the fall of 1963, I met Dave VanderHart and Bob Vaughan, who were enrolling in the same courses as I. We became good friends, even though Bob kept telling us that NMR was a dead field and we should all be doing Mössbauer spectroscopy instead! There were about 20 graduate students and postdocs in Prof. Gutowsky's group, working on everything from high-resolution NMR of liquids, to wide-line NMR of solids, to ESR. I was struggling to understand the spin density matrix, in order to calculate effects of chemical exchange in multiple pulse Carr–Purcell spin echo experiments on coupled spin systems. About six months into the project, I discovered that a postdoc with a desk just behind me, Ted Wells, was doing exactly the same thing! There was an euphoric time when every few days Prof. Gutowsky would suggest a new potential application, and Ted or I would come into the lab next morning with the appropriate detailed calculation.

The 30 MHz rf transmitter which I was privileged to use at Illinois merits mention. Its rf source was a battery powered World War II vintage oscillator, gated and amplified by a 30-tube circuit which was designed and built by previous generations of students (notably Donald Woessner and Bob McKay). I was warned that the transmitter would work only if it was mounted upside down. I didn't believe this until I had to replace a tube and tried to run the unit mounted right side up. It refused to run at all until I turned it back upside down, and a capacitor (rumored to have been soldered by T. C. Farrar) fell out!

Professor Gutowsky was very generous in providing support for several students to attend the Experimental Nuclear Magnetic Resonance Conference, held annually at the Mellon Institute in Pittsburgh. My first ENC was the 6th, in 1965. Everyone was bemoaning the fact that the meeting had become so large, with over 100 people attending! Richard Ernst announced and demonstrated the first use of Fourier transform NMR at this meeting. I overheard several eminent experts opine that this flashy new technique would never catch on, because phase corrections and other computer-intensive data processing procedures were too complicated, arbitrary, and expensive for the average spectroscopist.

In 1967 I spent a short postdoctoral period in Prof. Waugh's laboratory at MIT. He had just realized the implications of prolonged echo decays in multipulse solid echo experiments, and with Ulrich Haeberlen was developing average Hamiltonian theory. A promising graduate student, Alex Pines, was starting to explore applications to ^{13}C spectroscopy. I became involved with calculations of the chemical shift concertina, a pulse sequence designed to scale the chemical shift interaction in liquids. Since I was to be at MIT only six months before joining the faculty at the University of California, San Diego, I decided not to become involved with any experiments—this was a great mistake, since I missed the chance to learn first hand from Waugh, Pines, and R. G. Griffin how to do multipulse proton experiments on solids and ^{13}C experiments with cross polarization from protons.

Professor Waugh sponsored the attendance of several group members at a small NMR conference held every other year in New Hampshire. At the 1967 meeting, I was sitting at one late night discussion at the bar with Joseph Noggle and Karl Kuhlman, who had recently finished graduate work at Stanford with Prof. Baldeschwieler. The talk turned from density matrices to the newly announced Fourier transform method, and how it worked if the pulses were applied so closely that there wasn't enough time for full recovery of the magnetization. We thought for a while that with just two pulses, spin–lattice relaxation AFTER the second pulse would distort the signal beyond recognition. Soon we saw the error in this argument, and realized that if the first pulse were an inversion pulse, one could by means of FT measure the T_1 of each line in the spectrum. John Waugh realized the implication of this invention and convinced Melvin Klein (who at Berkeley had one of the few working FT systems) to try the experiment. My main contribution to the resulting paper² was the suggestion that a field gradient pulse, applied between the inversion and detection pulse to destroy unwanted coherence, could also be used in a Fourier transform spin echo sequence to measure diffusion coefficients of individual chemical species.

It was an enormous shock to leave the established programs of Professors Gutowsky and Waugh, and be faced with the task of developing an NMR program of my own at the University of California, San Diego. Then, as now, startup funds were inadequate: I was given a magnet and an oscilloscope, but had to assemble the rest of the spectrometer from components. And in those days, it was unheard of for any individual to monopolize a whole computer! A few companies, such as Magnion and NMR Specialties, provided complete pulsed spectrometers (at an outrageous price) but it was strictly caveat emptor. It seemed obvious at the time that I was in no position to compete in high-resolution solid state NMR, so while I was learning to build pulsed NMR spectrometers I modified

the departmental machine (a Varian HR-60) to do low power, liquid state Carr–Purcell spin echo experiments. This was my first exposure to the luxury of a phase sensitive detector, but it was disconcerting to see the FID change sign as the field drifted through resonance.

My experiences with chemical exchange at Illinois gave me a lasting interest in relaxation phenomena in coupled spin systems. The natural combination of this with FT methods of measuring T_1 led me to realize the importance of cross-correlation effects in dipolar relaxation of multispin systems. It was exciting to discover that cross-correlation effects in proton spin–lattice relaxation of planar molecules could be analyzed to fix the orientation of a fully anisotropic rotational diffusion tensor—conventional wisdom decreed that this was not possible.

The work on individual spectral densities for proton relaxation in scalar coupled systems set the stage for analogous experiments on systems with dipolar and quadrupolar couplings. I realized that by using deuterons instead of protons or carbon, the number of independent spectral densities to be determined was neatly matched by the number of readily measurable relaxation rates. Moreover, ‘everybody knew’ that quadrupole relaxation in fluid phases was governed exclusively by rotational motion. So, at first, it seemed that deuteron relaxation of small molecules in liquid crystals was the ideal way to study anisotropic rotational diffusion. However, it soon became clear that the anisotropic fluid was producing unusual effects. In fact, deuteron relaxation measurements of individual spectral densities proved to be as informative about collective processes, such as order director fluctuations, as they were about the effects of an orienting potential on single particle rotation.³

The orienting potential felt by a small molecule dissolved in a liquid crystal is just one example of a constrained environment. Much tighter motional constraints are imposed by confining the molecule to a crystal lattice. Channel inclusion compounds represent an interesting intermediate situation, in which motion of the guest provides unique information about the potential energy of host/guest interactions. With recent advances in computer simulation methods, it has become possible to calculate correlation functions of interest in NMR without recourse to simplified models. Equally important, multidimensional techniques for monitoring spin relaxation greatly

expand our ability to study motion over a wide range of timescales. Comparing the results of molecular dynamic simulations with experimental NMR data offers a new and powerful method to refine and improve the relevant potential functions. Inclusion compounds are particularly important in this context because the motion is often fast enough to yield pleasantly short relaxation times, and the computer time needed for a simulation scales only linearly with the number of guest molecules.

In my first 35 year involvement with NMR, the increase in its sophistication and scope of applications has been truly incredible. Nobody dreamt in 1962 that it would be possible to determine the fully anisotropic rotational diffusion tensor of a small molecule in a liquid crystal, let alone fully assign the proton spectrum of a small protein, obtain multidimensional high-resolution ^{13}C spectra of solids, or measure the distribution of rotational jump rates in a polymer. One can only guess what the next 50 years will bring.

Vold, Regitze R.: Bits and Pieces from My NMR Memoirs

Regitze R. Vold

University of California, San Diego, La Jolla, CA, USA

In Denmark, the era of NMR spectroscopy began in early 1962 with the arrival of the first analytical grade spectrometer—a Varian A-60. I still remember vividly my feeling of excitement on seeing this magic machine and the awe I felt when I was allowed to buy my first small bottle of deuterated chloroform, 25 ml for 500 DKr, ~\$70 US, corresponding to roughly half a month's salary for a research assistant at Denmark's Tekniske Højskole in Copenhagen. I had become aware of NMR spectroscopy as a chemical engineering student in the late 1950s, and having decided to do research in organic chemistry, I had started spending a lot of time in the library. It was here that my love affair with NMR began—stimulated mostly by Varian's advertisements for high-resolution 60 MHz spectrometers. (Or were some of them for just 40 MHz?) To me, those spectra with their pretty multiplets and sensible line intensities were clearly destined to become the most valuable probe of chemical structures, and I have since wondered how many other chemists were lured into NMR by those Varian advertisements on the back cover of every issue of the *Journal of the American Chemical Society*.

A special event took place in 1959 that educated many Danish chemists about the beauty of magnetic resonance. Carl Ballhausen had just spent a year or two at Bell Labs in New Jersey, and upon his return to Copenhagen he arranged to have his friend and colleague Bob Shulman give a series of six lectures on magnetic resonance at DTH. Bob started with a thorough explanation of the physical background, and I got quite scared—did I really have to understand that much physics to appreciate the 1:2:3 proton spectrum of ethanol? Much of those lectures was beyond my comprehension, but the resonance phenomenon was so clearly superior to 'ordinary' spectroscopy. And although those two different relaxation times were a complete mystery to me, I was intrigued by the fact that one could actually learn about molecular motion and 'chemical exchange' by measuring T_1 and T_2 values. Through these excellent lectures Bob Shulman showed us that NMR was not just a fantastic analytical tool, but also an exciting field of scientific inquiry.

Another important means of education of chemists in Europe was again due to Varian Associates, who for many years held NMR workshops¹ in Zürich, with lectures given by people like Norman Ramsey, Wes Anderson, and Jim Shoolery, and several other prominent members of the American NMR community. I proudly accepted an invitation to write an article about NMR for a newsletter published by Struers Kemiske Laboratorium in Copenhagen, who in return offered to pay my way to the 1961 NMR Workshop. It was a wonderful opportunity to learn about NMR, and those workshops unquestionably were responsible for getting many chemists started in NMR spectroscopy—as well as bringing Varian many spectrometer sales. I could hardly wait to finish

my dissertation, start my position at DTH, and do my own NMR research.

Alas, I had accepted a postdoctoral position at the University of New Mexico and an NMR spectrometer was not available in Albuquerque in 1962. In spite of this, I decided to stay in the US, I got married, and bided my time doing organic synthesis until I had a chance in 1965 to go to work with Ted Becker at NIH. Ted had *two* NMR spectrometers, a Varian A-60 as well as a Varian HR-60 with a lovely 0.2 Hz resolution, diligently maintained by Ted's assistant Bob Bradley, without whom NMR would never have made it at NIH. My first assignment was to work on the structure and chemical exchange in cytosine derivatives, and the most exciting event was our demonstration, together with nucleic acid expert Todd Miles, of Watson–Crick hydrogen bonding between purine and pyrimidine bases.² When late one evening in 1966 working on the A-60 in the sub-basement of Building # 2 we observed the 1:2:1 base pairing shift of the NH protons in a DMSO solution of 1-methylcytosine and 9-ethylguanine, we laughed and cried and danced around the spectrometer. NMR was indeed wonderful. To our chagrin we soon found out that a similar study was being conducted at MIT by Katz and Penman,³ and the two studies were published simultaneously.

A more monumental NMR event took place in 1966, namely the publication of Ernst and Anderson's paper on Fourier transform NMR spectroscopy.⁴ At the time I wondered why such an important paper had been relegated to the *Review of Scientific Instruments*, a respectable journal but hardly known for its groundbreaking publications in chemical physics. Many years later, at a dinner in La Jolla, Richard Ernst told me that he and Wes had tried in vain to get it published in the *Journal of Chemical Physics*, but that they had given up after receiving two unfavorable reviews! The promise of higher sensitivity available by using FT methods was not lost on chemists interested in low-abundance nuclei, like Ted Becker who wanted NIH to get involved in doing ¹³C NMR spectroscopy. Many discussions took place during meetings of the DC area's 'NMR-for-Lunch Bunch' and it soon became clear that the most expedient way to get going was to install a multichannel digitizer/signal averager on Tom Farrar's pulse rig at NBS. The next couple of years were memorable ones. Tom's spectrometer was housed in a shielded room that Tom had built during the days when the National Bureau of Standards was located on Connecticut Avenue in DC, right across the street from the Channel 7 television and radio station. The spectrometer was based on a Varian HR-60 magnet, which normally was run unlocked, and we had to convince solid state chemist Tom Farrar to reinstall the Super Stabilizer and the homogeneity shim coils. But at least he didn't try to convince graduate student Steve Druck and me to polish the pole faces with emery paper, as he had done during his years at Urbana. Tom taught us to find resonance by listening to a loudspeaker—it was a surprise to us how loud ¹³C enriched methyl iodide would sound as you swept through resonance. Except for the Tektronics 160 series pulsers and waveform generators, everything was homebuilt by Tom and his group at NBS. The probe was based on a design by Woessner, and rf units, power amplifiers, and their power supplies were constructed straight out of the *Radio Amateurs' Handbook*. It was an excellent NMR spectrometer, but it contained so many vacuum tubes that we exceeded the 'von Neumann limit', and we had to replace tubes constantly.

The configuration that finally allowed us to get ^{13}C FT spectra used a General Radio frequency synthesizer as a frequency source, a Fabritek 1074 signal averager with 4 K 18-bit words, and a Tally paper tape punch. The Fabritek signal averager was an excellent piece of equipment, full of sturdy magnetic core memory. But since no one at Fabritek had ever worried about rf sensitive detectors, they were not well shielded. It seemed for several months that Fabritek (soon to become Nicolet) did large amounts of development work for the first 1080 computer in our shielded room, but in return we got the earliest non-OEM 1080 computer to be installed. The paper tape was needed for the transport of free induction decays (three 4 K FIDs per tape) by car to NIH for Fourier transformation and other processing on the PDP-10 computer. The Tally mechanical tape punch worked fine, but the PDP-10 was equipped with a 'high speed' optical reader, and the registration did not always work well. This I/O problem taught Steve and me important aspects of 'data processing', namely the replacement of 'dropped channels' by hand. There were other interesting problems in those early days of FT NMR. Irv Salmeen from Mel Klein's lab at Berkeley had kindly given us his phase correction routine, although he warned us that it was somewhat slow. A classic understatement: when Steve and I executed it for the first time a strange quiet descended on the large computer room in Building #12. After a few minutes, a strange mumbling began to be heard around the room. All work being done by six to 10 people on the PDP-10 had come to a complete halt, and soon everyone, led by the system manager, came over to see what these idiot chemists were doing with their NMR spectra. The phase correction routine worked, but we were told in no uncertain terms that we had better replace that routine with something that didn't bring the whole PDP-10 to its knees for 20 min at a time.

During these years at NIH/NBS, I had become very interested in relaxation theory and measurements. One surprise to all of us involved in the ^{13}C liquids work was that T_2 was always much shorter than T_1 . According to most of the textbooks at the time $T_2 = T_1$ in nonviscous liquids, and that was definitely not what I found⁵ and the explanation was (of course) that spin-lattice relaxation of coupled protons shortened the ^{13}C T_2 value significantly. In order to understand this phenomenon, I contacted Bob Vold at UCSD. By a strange coincidence, he had just discovered a ' $\frac{3}{2}$ ' effect that made the proton T_2 longer than T_1 .⁶ We clearly complemented each other—it was love at first sight. During the next nearly 20 years we combined marriage and scientific collaboration, focusing on relaxation in coupled spin systems and developing better methods for characterization of molecular motion in condensed phases.⁷ We became particularly interested in combining measurements of rate constants for several relaxation modes⁷ in order to determine individual spectral densities of motion. One very useful trick was to use the Jeener–Broekaert pulse sequence^{8,9} or to combine selective and nonselective excitation of the deuteron doublet¹⁰ observed in macroscopically ordered phases. This way we could measure the relaxation times for both Zeeman and quadrupolar order, from which the spectral densities of motion $J_1(\omega_0)$ and $J_2(2\omega_0)$ could be determined. Our group was not the only one contributing to this field—several elegant studies of deuterium

relaxation measurements were published independently at more or less the same time.^{11–14} These methods proved particularly useful in studies of macroscopically ordered phases, because it had been shown^{15,16} that only $J_1(\omega_0)$ was sensitive to the small-angle librational motion in liquid crystals aligned along the magnetic field. This allowed us to demonstrate that pseudo-coherent modes of motion, the so-called director fluctuations, contribute significantly to spin-lattice relaxation in the radiofrequency range, and consequently that the cutoff wavelength for these modes had to be no longer than a molecular length.¹⁷ The main lesson of this work however, was that while relaxation measurements are admittedly very tedious, studies of the temperature, frequency, and orientation dependence of relaxation rates can be highly informative about details of molecular dynamics.

Biographical Sketch

Regitze R. Vold. b 1937, M.S. 1960, Chemical Engineering, Ph.D., 1962, Chemistry, Danmarks Tekniske Højskole, Copenhagen, Denmark. Postdoctoral work at the University of New Mexico, 1962–64. Staff fellow at the National Institutes of Health with Edwin D. Becker, 1965–71; research chemist, 1971–82, and Professor of Chemistry, 1982–present, at the University of California, San Diego, USA. Approx. 120 publications. Research specialties: relaxation in multilevel spin systems, especially of ^2H , and molecular motion in liquid crystals, inclusion compounds, proteins, and paramagnetic materials.

van der Waals, J. H.: Gorter's Footprints on the Trail That Led to Magnetic Resonance

J. H. van der Waals

Leiden University, Leiden, The Netherlands

The Dutch physicist Cornelis Jacobus Gorter (1907–80) was the first to demonstrate the phenomenon of paramagnetic relaxation. Understanding its implications, he recognized that—at least in principle—the magnetic dipole transitions between the Zeeman components of a nuclear spin system might be observed as a resonance effect. To his regret, Gorter's attempts at observing such resonances in a solid, made in the years 1936 and 1942, remained fruitless. However, since Zavoisky a few years later reported a successful electron spin resonance experiment (1945), and Bloch, Hansen, and Packard, and Purcell, Torrey, and Pound reported nuclear magnetic resonance experiments (1946), it seems appropriate to give a brief historical sketch of Gorter's seminal efforts in this field (Figure 1).

Gorter studied in Leiden where at the age of 25 years he defended a Ph.D. thesis entitled 'Paramagnetische Eigenschappen von Salzen' (paramagnetic properties of salts). He then began his professional career at the renowned but modest physics laboratory of the Teyler's foundation in Haarlem,

Figure 1 The Dutch physicist Cornelis Jacobus Gorter (Photograph by E. de Jong)

moved as reader to the University of Groningen in 1936, and was appointed Professor of Physics at the University of Amsterdam in 1940, to a chair formerly held by Zeeman. While in Groningen he had a very fruitful collaboration with his colleague in theoretical physics, R. de L. Kronig; during the difficult war years in Amsterdam he struggled to keep his research going with the help of bright young students, amongst whom was L. J. F. Broer. Gorter's true allegiance, however, remained with the Kamerlingh Onnes Laboratory in Leiden with, at the time, its almost unique low-temperature facilities. Thus, shortly after the war, Gorter seized the opportunity to move from Amsterdam to Leiden, where in 1948 he became the Director of the Kamerlingh Onnes Laboratory. In retrospect, this promotion must have been a challenge for an ambitious young physicist, but also a mixed blessing to be burdened with the directorship of a famous physics institute in those years just after World War II. While physics in the United States had continued to flourish in places like Harvard or the MIT Radiation Laboratory, the situation in Holland after five years of war was dismal. There is no question that Gorter and some of the leading scientists of his generation in Holland were saddled with tasks that interfered with their creative work.

Gorter might, perhaps, best be characterized as one of the last true, general physicists; a man who frowned on specialization and considered almost the whole of physics as his playground. Together with his Ph.D. students or colleagues in theoretical physics, he made major contributions in subjects as diverse as paramagnetic relaxation, nuclear orientation, and the anisotropy of γ - and β -emissions, superconductivity, superfluidity, and the Senftleben effect. Thus, one may wonder, as did Gorter himself in his acceptance speech when honoured with the Fritz London award in 1967, whether he had perhaps spread his efforts too thinly.¹

I shall merely consider here Gorter's efforts in relation to magnetic resonance. In his student days, Gorter had already been impressed by Ehrenfest's argument² that the validity of the Curie–Langevin formula for the magnetization of a paramagnetic material implied relaxation processes induced by thermal motion. After a preliminary, unsuccessful experiment by Breit and Kamerlingh Onnes, Gorter became the first to demonstrate the reality of such relaxation.³ Heeding Ehrenfest's suggestion, he measured the heat effects accompanying the (electron–spin lattice) relaxation of Fe^{3+} , Cr^{3+} , V^{3+} , Ti^{3+} , and Gd^{3+} ions in alum crystals placed in an rf magnetic field ($\nu = 10\text{--}21\text{ MHz}$, $B_1 = 0.5\text{--}0.8\text{ mT}$) in a calorimeter cooled by boiling hydrogen or nitrogen.

In parallel with these experiments, Gorter and Kronig worked on the theory of absorption and dispersion in paramagnetic crystals under the influence of an alternating magnetic field.⁴ Their work was inspired by Debye's treatment of the dielectric behavior of an assembly of rigid dipoles subject to frictional forces and Brownian motion. Gorter realized that when a system of spins $S = \frac{1}{2}$ (or $I = \frac{1}{2}$) is placed in a constant magnetic field B_0 and subjected to a second, alternating magnetic field perpendicular to B_0 , its response can be described by the real and imaginary parts of the magnetic susceptibility, as sketched in Figure 2. The figure, which is a copy of Gorter and Broer's original drawing,⁵ shows the now familiar fact that at the frequency ν_0 where the resonance condition $h\nu_0 \approx \mu B_0$ is fulfilled, a magnetic dipole transition occurs which manifests itself by a maximum in the absorption

Figure 2 Absorption A and susceptibility χ as a function of frequency ν . The halfwidth δ has been taken equal to $0.05\nu_0$. Reproduced from Gorter and Broer⁵ [in current terminology χ denotes the real part (χ') of the susceptibility and A is proportional to its imaginary part (χ'')]. Reproduced by permission of Elsevier Science Publishers

A , accompanied by a ‘jump’, $\Delta\chi$, in the (real part of the) susceptibility χ . According to Gorter and Broer, this jump, is given by

$$\Delta\chi/\chi_0 = \nu_0/\delta \quad (1)$$

where δ denotes the halfwidth of the spectral transition and χ_0 the static susceptibility due to the spins concerned. If thermal equilibrium obtains, then

$$\chi_0 = N\mu^2/3kT \quad (2)$$

where N is the number of spins per gram and μ is the spin magnetic moment.

Because of the limitation in frequency of the rf equipment at his disposal, Gorter’s experiments on the relaxation of paramagnetic salts in strong external fields⁶ were restricted to frequencies below those where resonance occurs as depicted in Figure 2. However, Gorter realized that, because of the smallness of the nuclear magnetic moment compared with that of an electron, his equipment should be well suited to investigate *nuclear* paramagnetic relaxation phenomena in the resonance region depicted in Figure 2. Using the calorimetric method that had proved so successful in the demonstration of electron paramagnetic relaxation the same year (1936), Gorter made his first, negative, attempt to detect magnetic resonance transitions of ^1H and ^7Li nuclei in $\text{K}[\text{Al}(\text{SO}_4)_2] \cdot 12\text{H}_2\text{O}$ (alum) and LiF crystals, respectively.⁷ In these experiments, carried out at liquid hydrogen temperature (14–20 K), the crystals were subjected to a 20 MHz alternating field with a strength B_1 as high as 1 mT and a constant field that could be varied between 0 and 1.4 T. Provided Boltzmann equilibrium was maintained between the $m = \pm\frac{1}{2}$ spin states at the temperature of the lattice, Gorter expected to observe a temperature rise of $0.3\text{ }^\circ\text{C min}^{-1}$ in the experiment on protons in alum. However, the actual temperature rise was at most 1% of this estimate and remained hidden in the background due to the heat leakage of the calorimeter. With our present knowledge it is clear that Gorter’s explanation . . .

The only reasonable explanation of this negative result is that the absorption of energy by the nuclear spin disturbs the Boltzmann distribution over the nuclear energy levels

. . . is the correct one. He further concluded that the ‘nuclear temperature’ in the experiment must have been in excess of 1400 K and that the spin–lattice relaxation time was longer than 10^{-2} s. Gorter’s reasoning, in a sense, anticipated the thermodynamic interpretation of paramagnetic relaxation phenomena by Casimir and du Pré.⁸ These authors were the first to formulate clearly that it is reasonable to assume that in the relaxation experiments thermal equilibrium is rapidly established within the lattice and spin systems individually, each at its own temperature, whereas the relaxation reflects the slow heat transfer between the two systems.

A year later, in September 1937, Gorter visited Rabi’s laboratory at Columbia University. It proved a fateful visit for both parties and a boost for science. Rabi and his collaborators were pioneers in molecular beam techniques. In their experiments designed to determine the sign of the magnetic moments of the proton and deuteron,⁹ changes of the quantum states of hydrogen and deuterium atoms in the incoming beam were effected by passing the beam through a region in which (dc) electric currents in a set of parallel wires generated a highly anisotropic magnetic field pattern. In a coordinate system moving with a given atom, the applied field T then varies in direction and strength as a function of time. If the field pattern relative to the direction of propagation is chosen suitably, nonadiabatic changes in the magnetic quantum number result, from which by a somewhat involved argument the *sign* of the magnetic moment of the nucleus may be derived.⁹ The absolute *magnitude* of the nuclear moment, however, must be determined via another beam experiment. Because, as the authors of Ref. 9 stated:

Since the form of the field T [felt by a particular nucleus] is not known exactly it is not possible to calculate α [an angle specifying the change in quantum state] as a function of the field and of the velocity. There will also be a different value of α for every atomic velocity. We cannot, therefore, begin by setting the field at some particular value and expect to find nonadiabatic transitions.

In other words, in the configuration in which it existed in 1936, with all applied fields of a static nature in the laboratory frame, the beam equipment was not suited for carrying out quantitative magnetic resonance experiments.

In January 1938, a few months after Gorter’s visit, the Columbia group heralded the first successful nuclear magnetic resonance experiment. It was carried out on Li and Cl nuclei in a beam of LiCl molecules, and reported in a Letter entitled ‘A New Method of Measuring Nuclear Moment’.¹⁰ From Gorter’s own account,^{1,5} contemporary sources, and the acknowledgement at the end of the Letter,¹⁰ it transpires that Gorter had provided a stimulus which was crucial for this success. Apparently he had asked why, instead of trying to change the Zeeman state of the particles by passing the beam through a highly anisotropic but poorly-defined static field, this was not done by irradiating a magnetic dipole transition between two of the Zeeman states—as in his own recent, unsuccessful calorimetric experiment! This means that between the first, inhomogeneous magnetic field and the refocusing field of the earlier experimental configuration,⁹ the beam should be passed through a region with a constant field plus a weak radiofrequency field at right angles to it that could be generated by a simple coil driven at the resonance

frequency. This worked, and six years later Rabi was awarded the Nobel Prize in Physics for his superb beam experiments.

As Gorter saw, Rabi's method had the great advantage that the absorptive ($m \rightarrow m'$) and stimulated emission ($m' \rightarrow m$) transitions have an additive effect on the signal of the beam detector. In contrast, in his own calorimetric experiment they had cancelled one another out. Now, with nuclear magnetic resonance no longer being a figment of the physicist's imagination, Gorter renewed his attempts to detect it in a solid. Or, in his own words:⁵

The success however obtained by Rabi and his collaborators in 1938 when they combined, on our instigation, the principle of a constant and an oscillating magnetic field perpendicular to each other with their marvellous molecular beam technique, encouraged us to continue the experiments we had undertaken along a somewhat different line. These experiments again related to nuclear magnetic spins in solids, but as the transfer of absorbed energy to the crystal lattice had appeared to be too slow, they aimed at observing the anomalous dispersion which must occur in the neighbourhood of a spectral line. This anomalous dispersion should lead to a rather sharp jump in the susceptibility (compare Figure 2).

In their publication⁵ Gorter and Broer then refer to equations (1) and (2) to estimate the magnitude of this jump and somewhat glibly pass over the effect of saturation. If the thermal contact between spins and lattice is insufficient and the spin temperature becomes very high due to saturation, χ_0 tends to zero and so does $\Delta\chi$ according to equation (1) and (2). Yet, they must have realized that with increasing saturation the vertical distance between the two extremes of χ in Figure 2 goes to a finite, asymptotic value, although the absorption A vanishes (for a discussion in modern terminology, cf. Abragam¹¹).

The susceptibility experiments by Gorter and Broer were carried out on the ^7Li and ^{19}F nuclei in LiCl and KF polycrystalline powders in which the coil of a resonant circuit operating at 3.7 MHz was embedded. These particular substances were chosen in order to minimize the linewidth δ by keeping the local fields due to the neighboring counterions (Cl or K) small. After preliminary experimentation at the boiling point of nitrogen in the Zeeman Laboratory of the University of Amsterdam, the final experiments were carried out at the Kamerlingh Onnes Laboratory at the boiling points of hydrogen (LiCl and KF) and helium (LiCl).

On the basis of a (realistic) estimate of the linewidth due to Kronig and Bouwkamp,¹² a susceptibility change leading to a frequency shift of the oscillator of ≈ 80 Hz was expected on passing with the magnetic field through resonance in the experiment on LiCl in helium, provided the static susceptibility χ_0 was that predicted by the Langevin formula for a temperature of 4.2 K. However, no shift was detected and it must have remained smaller than about 1 Hz. Another experiment, carried out at Casimir's suggestion, in which the sample was cooled down from room temperature to 4.2 K in a strong stationary field of 1 T, was equally unsuccessful. The authors concluded that, as in Gorter's earlier calorimetric experiment, the negative result was most likely due to slow spin-lattice relaxation. They wrote:

The time characterizing the establishment of equality between the "nuclear spin temperature" and the lattice temperature would have to be considerably larger than 10^3 seconds at the low temperatures.

It is sad that Gorter came so close to making a great discovery and then gave up. Bloembergen later determined

the relaxation time T_1 in the LiCl crystals used by Gorter and Broer, and found $T_1 = 600$ s at 2.1 K. So, if the estimate given in the above quotation was realistic, the authors might have observed a small effect. Although a reasonable knowhow of *electron* paramagnetic relaxation existed, no quantitative information whatsoever was available on *nuclear* relaxation, and no one was aware of the effect paramagnetic impurities might have. On the basis of Waller's¹³ theoretical analysis, however, there was every reason to suspect that the Li nuclei in a pure, diamagnetic LiCl crystal would be very slow in coming to thermal equilibrium with the lattice. On considering this dearth of information, the authors might have been well advised to try a few, quite different samples. But hindsight is easy, and the wartime conditions in 1942 were far from conducive to experiments in physics.

Gorter had the advantage of starting his work in the intellectual company of theoretical physicists like Kronig, Casimir, and Kramers, who were all actively interested in problems in magnetism. Together, they had by 1940 arrived at a reasonable understanding of electron paramagnetic relaxation. When, during the later years of World War II further experimentation was out of the question, Gorter gathered his knowledge of the field in a small monograph entitled 'Paramagnetic Relaxation'.¹⁴

In '*Bloembergen, Nicolaas: My Early Years in NMR, 1946-48*', Bloembergen gives a lucid description of the realization of NMR in condensed phase by the groups at Harvard and Stanford in 1945. This, together with the discovery of electron paramagnetic resonance by Zavoiskii¹⁵ and the formulation of the Bloch equations, opened an entirely new door for looking at the mysteries of relaxation processes in ensembles of spins. Gorter's book, therefore, soon became dated. However, his interest in the field by no means waned, as is apparent from Bloembergen's account. For example, he discovered the phenomenon of exchange narrowing and discussed it with Van Vleck.¹⁶ He was also the first to identify cross relaxation ('third relaxation' in Gorter's terminology),¹⁷ a process for which Bloembergen et al.¹⁸ gave a detailed explanation and which constitutes one of the cornerstones of today's pulsed NMR techniques.

Research physicist and subsequently Associate Director of Research with Shell, 1946–67; Professor of Physics, University of Leiden, 1967–89. Worked as an undergraduate in C. J. Gorter's laboratory (1941); shared an office with Harden McConnell at Shell Development Co., Emeryville, when the Varian #1 NMR spectrometer arrived (1953–54). Current research interest: study of excited states of molecules, frequently by EPR.

Wagner, Gerhard: NMR of Proteins

Gerhard Wagner

Harvard Medical School, Cambridge, MA, USA

While I was working as a physics student on my diploma thesis at the Technical University of Munich on the Mössbauer effect of iron-containing proteins, I first became aware of the field of NMR as a result of my supervisor's (Adalbert Mayer) leaving for a sabbatical to learn NMR in Robert Shulman's group at Bell Labs. After graduation (1973), I joined Kurt Wüthrich's group in Zürich as a Ph.D. student working in the area of biological NMR, essentially against the advice of some of my supervisors who thought that everything had already been done in the field of NMR. I thought so too, but was attracted by biological applications and the phenomena of relaxation, which I didn't understand.

MOBILITY OF AROMATIC SIDE CHAINS IN BPTI

I started working theoretically with molecular orbital calculations of porphyrin systems with the goal of understanding chemical shifts in heme proteins. Kurt Wüthrich convinced me to do some experimental work, and so I took over a project from one of the graduate students, André Masson, who was finishing up. He had been working with the basic pancreatic trypsin inhibitor (BPTI) using the 220 MHz spectrometer at the ETH and had studied NH exchange in D₂O and the thermal unfolding of the protein. When he handed the project over to me, he mentioned that he had essentially understood most of the spectrum, except for an amorphous bump in the base line that could be seen downfield from the aromatic resonances. For some unknown reason it always looked different from one spectrum to another.

This amorphous signal became the main subject of my Ph.D. thesis. Soon I tried to assign the aromatic spectrum of BPTI with spin decoupling in CW experiments on a Bruker 270 MHz spectrometer. Some intensity was missing from the 36 aromatic protons of BPTI. I presented this finding at the 6th International Conference on Magnetic Resonance in Biological Systems in Kandersteg (1974). At the same session Grayson Snyder, a graduate student of Brian Sykes, presented assignments of tyrosine side chains obtained from chemical modifications. He had found that one of the tyrosines, Tyr35, showed four one-proton resonances and appeared to be immobilized. After the conference, Prof. Zeev Luz spent several weeks at the ETH as a guest of Kurt Wüthrich. His knowledge enhanced our understanding and awareness of dynamic processes. As a consequence of discussions with Luz, I did what sounds trivial now but wasn't then—I recorded the spectra of BPTI in D₂O below room temperature. The broad baseline bump disappeared and five one-proton resonances of an immobilized phenylalanine side chain emerged from the noise, accounting for the previously missing intensity,^{1,2} and the sidechain could be reversibly mobilized or immobilized by temperature variation. At that time, other NMR groups were also discussing that most aromatic sidechains could be rotating in proteins, despite their rigid appearance in crystal

structures.^{3,4} The clear transition from slow to rapid rotation was first observed in BPTI. The mobility of the aromatic sidechains in BPTI has subsequently become the subject of numerous experimental and theoretical studies.

SEQUENTIAL ASSIGNMENTS

After the meeting in Kandersteg, Dr. Antonio DeMarco joined Wüthrich's group as a postdoc. He implemented methods of difference decoupling and applied resolution enhancement techniques, such as the convolution difference method developed in the Oxford group, and he introduced the sine-bell multiplication which is still very popular today. These techniques were used for assigning methyl resonances in BPTI. Concurrently, Dr. Regula Keller started measuring NOEs between heme resonances in cytochromes and was able to assign all resonances based on a knowledge of the covalent structure of the heme group,⁵ and Sidney Gordon, on sabbatical leave in Wüthrich's group, began applying Solomon's transient NOE experiments to proteins.⁶ Also, at that time, Andreas Dubs, an undergraduate student, joined the group to work on his diploma thesis.

Andreas, who had attended a biophysics course I was teaching, had built a labquib model of BPTI as part of his course work. During the ensuing diploma work, he and I spent a large amount of time inspecting the plastic model and exploring the geometry of the molecule. This was a key component in the development of the sequential assignment methods. As the primary work of his thesis Andreas measured NOEs from the well-resolved slowly exchanging amide protons. When using short irradiation times, there was usually a single H^α resonance that showed a much larger NOE than anything else. Only after a lengthy inspection of the BPTI model did we detect the almost trivial fact that the H^α of the preceding residue was generally nearest to an H^N, and that other H^α protons were a significantly larger distance away. We could show analytically that the initial slope of the NOE build-up curves of truncated driven NOEs were directly proportional to r^{-6} and could be related directly to molecular structure.⁷

This identification of the sequential d_{αN} NOE, together with the intraresidue connectivities obtained from spin decoupling, quickly led to sequence specific assignments for 15 β-sheet residues.⁸ At the same time, we became aware of different sequential NOEs in helices and established an initial statistic of characteristic distances in β-sheets and helices.⁸ This was later elaborated by a new graduate student, Martin Billeter.⁹ The initial sequential assignment method was limited to D₂O experiments, however, because our spectrometer was not flexible enough to presaturate the water and selectively irradiate a protein resonance to develop NOE. Further progress had to await the development of 2D NMR. This eventually led to the complete assignment of the BPTI spectrum¹⁰ and the development of methods to solve protein solution structures as described by Kurt Wüthrich elsewhere in this Encyclopedia (*Biological Macromolecules: Structure Determination in Solution*).

COUPLING CONSTANTS AND TRIPLE RESONANCE EXPERIMENTS

In 1986 and 1987, when I set up a new NMR lab at the University of Michigan, I had as my top priorities developing

better methods for measuring coupling constants and learning more about relaxation. I had the feeling that a reverse probe that could pulse ^{13}C as well as ^{15}N would be useful for this aspect, so in the fall of 1986, when I ordered my new 500 MHz spectrometer from General Electric, I also ordered a custom built reverse detection ^1H - ^{15}N - ^{13}C triple resonance probe. My idea was to measure heteronuclear vicinal coupling constants by some means that would allow us to add and subtract in-phase and antiphase doublets, so that each doublet component could be observed separately.

When the probe was eventually delivered, my postdoc Guy Montelione and I discussed how to use it for such measurements of ^1H - ^{15}N coupling constants. In one of these discussions, in the fall of 1988, we realized that we would not need the triple resonance probe if we ran a 2D experiment that contained cross peaks between amide and β -protons using a ^{15}N -enriched protein. If we did not mix the nitrogen populations between evolution and detection, we could separate the two doublet components by the large ^1H - ^{15}N one-bond coupling constant and measure the vicinal coupling constant without overlap.¹¹

After discovering this method, we realized that it utilized the same principle we had ourselves previously used to measure ^{113}Cd - ^1H coupling constants in metallothionein.¹² I presented these results at the UCLA Symposium at Park City (1989). During the conference and on the way home I kept thinking about an extension to measure homonuclear coupling constants. The triple resonance probe could be used for this purpose. But an experiment had to be designed that would achieve cross peaks between the C^α carbon and the amide proton without mixing the populations of the H^α proton.

My first attempt was to try to achieve this using the long-range coupling between C^α and H^N -selective proton pulse. Guy Montelione proposed using a relayed transfer via the ^{15}N nucleus and using a TANGO pulse, a 90° pulse selective for the amide proton for the final coherence transfer. This sequence, developed by Guy, showed the desired pattern for the intraresidue H^N - C^α cross peak.¹³ In addition, however, it showed a cross peak between the H^N and the C^α of the preceding residue, which we discovered was due to the two-bond coupling between the nitrogen and the C^α of the preceding residue.¹⁴ This unexpected observation of a sequential triple-resonance cross peak opened a new route to achieving sequence specific assignments in ^{15}N - and ^{13}C -labeled proteins. These results were first presented in

the summer of 1989 at an International Conference of the Royal Society of Chemistry in Warwick. Since that time, numerous improvements in this technology have appeared in the literature.

G. Wagner. b 1945. Diplom., 1972, Physics, Technische Universität München, Germany, Ph.D., 1977, Biophysics, ETH Zürich (supervisor Kurt Wüthrich). Postdoctoral work with John Waugh, 1978–79. Privatdozent ETH Zürich, 1983; Faculty, Biophysics Research Division, University of Michigan, Ann Arbor, 1987–90; Faculty, Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, 1990–present. Approximately 180 publications. Research interests include NMR relaxation, protein dynamics and structure, protein interactions.

Warren, Warren S.: The NMR–Optics Connection

Warren S. Warren

Princeton University, Princeton, NJ, USA

Magnetic resonance is an extraordinarily powerful technique, with broad applications in physics, chemistry, and medicine. From a theoretician's perspective, NMR has tremendous advantages: the Hamiltonian is known and simple, quantum mechanical equations of motion can be solved (essentially exactly and often by hand), and the radiofrequency technology exists to create virtually any pulse sequence that can be conjectured.

There are none of these advantages in most other regions of the electromagnetic spectrum, but that has not prevented the daring (or foolish) from trying to extend NMR techniques to other forms of spectroscopy. Nowhere are the contributions more apparent than in laser spectroscopy, which owes much of its utility to the work of magnetic resonance 'émigrés'. The names of Bloembergen, Hahn, and Hartmann are just as recognizable in the laser community as they are in NMR—but not for the same reasons; by the mid-1960s these three men had created most of what we now call coherent optical spectroscopy. By 1980, Michael Fayer, Charles Harris, Douwe Wiersma, and Ahmed Zewail were using optical analogs of simple NMR and ESR sequences (mainly the photon echo and stimulated echo) to characterize relaxation and dynamics in isolated molecules, liquids, and solids. They all acquired their understanding of coherence from work in optically detected magnetic resonance; elegant work from their groups continues today.

The lure of doing something other than NMR was quite strong for me by 1980. If there were a *Guinness Book of Records* entry for the most complicated radiation pulse sequence ever successfully executed, it would belong to the multiple quantum selective excitation sequences I used as a graduate student in Alex Pines's laboratory. Alex's enthusiasm had attracted a truly outstanding group of students (I worked mostly with Dan Weitekamp, Gary Drobny, Steve Sinton, Jim Murdoch, and Jau Tang). There was much creative energy in that group (read that as 'we argued a lot; we were trying to understand some pretty complex concepts'). Even by the standards of the time, we had relatively poor equipment; I remember shimmying for days on the group's 180 MHz ' γ machine' and being thrilled ultimately to produce a 25 Hz wideline shape. We did, however, have a spectacular pulse programmer (designed before my time by David Rubin). For a good measure of the level of sophistication of NMR theory and hardware 15 years ago, consider this: we could make the γ give a 4096-pulse selective excitation sequence, with pulse timings and phases predicted precisely by average Hamiltonian theory. If the experimental spectrum did not agree with our predictions, the *spectrometer* had to be tweaked—because the theory had to be right.

Selective excitation experiments eventually worked on a wide variety of samples, but I couldn't imagine what I would want to do next (an 8192-pulse sequence?). At least at first glance, it seemed obvious that if optical analogs of 20- or 30-year-old NMR sequences were useful, analogs of dipolar line

narrowing or multiple quantum sequences could be valuable as well. Alex has always been fascinated with optics; he almost took a postdoc with Peter Rentzepis to become a laser spectroscopist. He suggested I consider working with Bloembergen, Fayer, or Zewail. I quickly discovered what had prevented laser spectroscopists from using more recent NMR innovations. Photon echoes and stimulated echoes work because the phases of the pulses do not matter. In fact, most laser spectroscopists had only a vague idea of the *meaning* of the phase of a laser pulse—the vast majority of laser experiments, then and now, really used laser pulses only as intense flashlights. Zewail, Fayer, and Harris understood phase quite well; they just did not know how to control it. Nobody had ever generated a sequence as complex as two nonoverlapping pulses with a controllable phase relationship between the pulses.

There was one partial exception. A few years earlier, Zewail and one of his students (Tom Orlowski) had used an acoustooptic modulator to chop pieces out of a continuous laser beam for three-pulse echo experiments. An acoustooptic modulator uses radiofrequency pulses to diffract light into a different direction. The frequency of the diffracted light is the sum of the input laser frequency (5×10^{14} Hz for red light) and the radiofrequency (500 MHz for common devices). Zewail showed me the commercial rf pulse driver they used, which just gated continuous rf with a mixer, thereby obviously (to an NMR spectroscopist) always giving the same phase of rf pulse. Their three-pulse laser experiment would have failed if the optical phases had been random; they had assumed the pulses were in phase, and this turned out to be correct.

I knew nothing about optics, but I knew that NMR spectrometers often make phase-shifted rf pulses at a low frequency, then mix them up to the final output frequency. I also knew that any device that produced an output at the sum of the frequencies of the two inputs was multiplying the two waves together like a single sideband mixer. To me, this meant that phase-shifting the rf pulses would have to phase-shift the laser pulses. In effect, the transmitter section of an NMR spectrometer could control a laser pulse sequence—phase and all.

Zewail was a bit skeptical, with good reason. After all, I had never turned on a laser. So one afternoon in Berkeley, I sat down for several hours with Charles Harris. Eventually he concluded that the idea had to work. I went to work with Zewail, who steered me in the right directions and within a few months we did the first pulsed experiments with full phase control. We could make rectangular laser pulses with ~ 10 ns time resolution and peak powers of less than 1 W—good enough for small molecules in the gas phase, but far too slow and weak for most interesting applications. Over the last decade, a variety of groups (including my own) have figured out how to do ps or fs resolution phase-shifting; how to shape laser pulses with better than 30 fs time resolution and peak powers of 10^9 W; and how to use such pulses to create population inversions, enhance signals, or monitor molecular evolution.¹

I still do both NMR and laser experiments, and I have often found this dual perspective helpful. Some ideas can be transferred directly between NMR and optics. When I started thinking about pulse shaping, the technology did not exist to make complex pulse shapes with lasers, but the MRI community was already using empirically derived shapes

for improved images. So most of our initial applications of shaped pulses were in NMR. For example, the $\text{sech}(\alpha t)^{1+5i}$ pulse shape (equivalently, a hyperbolic secant pulse with a hyperbolic tangent frequency sweep) was first derived in an optics textbook in 1975, first used in an NMR experiment by Hoult and Silver in 1984, and first used in laser experiments by my group in 1986. In addition, radiation damping in NMR was the forerunner of optical superradiance, which has been very extensively explored. That work helped us greatly when we started re-examining radiation damping a few years ago.

The other useful feature of my continued optics connection is a healthy skepticism for theory. The Hamiltonian is essentially never known completely in optics, and many of the assumptions that make NMR spectra easy to interpret do not work. When experiment and theory disagree in laser work, usually the experiment is right. About four years ago, we started doing very simple two-dimensional NMR experiments on samples such as pure water and getting ‘theoretically impossible’ experimental results. This time we were *not* seeing instrumental artifacts—even though we did not understand what was happening for several years. We found some gaps in the conventional (density matrix) framework of high-resolution NMR in solution, which eventually led to our observation of intermolecular multiple quantum coherences due to long-range dipole–dipole couplings (see *Concentrated Solution Effects*).

I continue to recommend NMR training as a great background for other kinds of spectroscopy (as well as an

important field in its own right). The complexities in optical experiments are severe, and there are quite a few NMR spectroscopists who dabbled with lasers for a few years and later turned back to spins. Nonetheless, many scientists expect substantial accomplishments in molecular reaction control with lasers over the next few years. When this happens, it will be due in no small part to the work of the magnetic resonance émigrés and NMR–laser dual citizens.

Waugh, John S.: Alchemy of Nuclear Spins

John S. Waugh

Massachusetts Institute of Technology, Cambridge, MA, USA

INTRODUCTION

In these personal reminiscences I have emphasized a few events and researches which seemed relatively important or were especially interesting to me, most prominently the development of coherent averaging and average Hamiltonians. A number of other subjects are mentioned briefly, most of them with representative literature references, but a great many things have been left out altogether. This selectivity means that many students and colleagues have gone unmentioned; I apologize to them in advance.

EDUCATION: UP TO 1953

I first heard of NMR in 1949 from my research adviser, Don Yost, who had read about it and had an undergraduate thesis student, Floyd Humphrey, building a marginal oscillator. Yost's way of learning about interesting new developments was to inveigle a student into working on it. When Humphrey graduated, I seized the opportunity to become the NMR student. The closest real spectrometer was in Felix Bloch's laboratory at Stanford, and I would have felt it presumptuous, as well as too expensive, to visit there. Subsequently, during vacation trips to the East, I visited the Harvard Labs, and was encouraged by the graduate students, especially Fred Reif and George Benedek. After reading the still rather scarce literature I decided to build a bridge-type spectrometer with field modulation and lock-in detection, in the style of Nico Bloembergen's Harvard thesis. I borrowed an electromagnet from the cosmic ray physicists and had the shop make new pole pieces. The power supply was a set of World War II surplus submarine batteries. A very linear sweep was generated by adding high-resistance windings on the pole pieces driven by a novel circuit using a thyratron: this was the subject of my first scientific publication.¹ This spectrometer was an advance over Bloembergen's in that it recorded its spectra on a strip chart recorder. I loved electronics and had a wonderful time building this machine.

I was greatly stimulated by the atmosphere at Caltech, where a student could mingle informally with the most brilliant and famous scientists. My first exposure to quantum mechanics came in my second year when Richard Feynman arrived from Cornell, an instant celebrity, and took over the standard introductory course in the Physics Department. Most of the faculty and postdocs showed up and spent the term trying to impress Feynman with their smart questions. It was no place for a green chemistry student, but I worked enormously hard and, merely by surviving, convinced myself that I could understand theory. (Feynman did everything with path

integrals or, as he called them, 'Broadway' integrals: I taught myself about Schrödinger and Heisenberg later.)

I had to find a subject for a thesis. The chemical shift was obviously going to be important for chemistry, but the homogeneity of my magnet was not good enough for that. I chanced to learn from Richard Newman, a postdoc with Richard Badger, that the very short (2.26 Å) hydrogen bond of the bifluoride ion might mean the proton was in a single potential well. This sounded very promising for a Pake-style study, since we all knew the advantages of protons and ^{19}F for NMR. The spectra were noisy but agreed with my calculations for a symmetric molecule. Of course motional averaging would make both H-F distances the same, as one says nowadays, 'on the NMR timescale'. The value of $\langle r_{\text{HF}}^{-6} \rangle$ measured from the spectra, however, was inconsistent with a structure in which the proton spent very much of its time away from the center.

Herb Gutowsky was organizing a session on NMR for an ACS meeting in Atlantic City for the fall of 1952, and invited Don Yost to contribute. Yost suggested that I go, since I was expecting to defend my thesis just before the meeting and was planning a vacation trip East. This was my first scientific meeting. There were papers by, among others, Ben Dailey, George Pake, Sam Weissman, and Brevis Bleaney. Russell Varian asked a number of questions. At the time no paper could be presented at an ACS meeting unless at least one of the authors was a member of the society. Neither Yost nor I qualified, so we added Floyd Humphrey as a co-author and that is the way the paper was finally published.²

I spent the following year as a postdoc with Robert Bacher doing radiocarbon dating, served as the resident associate (housemother) for one of the undergraduate houses, bought a yellow convertible, and generally spent a highly social year. I had several interviews for employment, accepted an offer from MIT, and went East in the summer of 1953. Actually the move was part of an NMR player trade: Jack Roberts (Professor) for Waugh (Instructor) and undisclosed cash.

APPLICATIONS OF NMR AT MIT: 1953–64

In 1953, fledgling academic scientists were not given the kind of dowry that came to be expected later. I had an office but no laboratory and no research grant. I cannot imagine how I would have succeeded without the extraordinary kindness of Francis Bitter, who let me use a laboratory under the lobby of Building 6, and arranged for me to join the Research Laboratory of Electronics. This was the postwar outgrowth of the MIT Radiation Laboratory, where most of the wartime American radar development had occurred. Members had access to their excellent shops and stockrooms, and it was with that support that I built some equipment and continued some researches in NMR of solids.

By about this time Varian Associates had begun selling NMR spectrometers for studying liquids. In 1955 Dick Lord persuaded the rest of the Chemistry Department that this kind of NMR was important, and got them to spend \$25 000 on the latest 40 MHz spectrometer. I, being the local expert, was put in charge. This meant that, in addition to working with my own students, I became a consultant on the application of NMR to all manner of chemical problems, leading to a number of rewarding collaborations with colleagues. I was also stimulated by the activity up the river at Harvard. Ed

Purcell, Charlie Slichter, and Anatole Abragam gave lectures, and I had continuing contact with Aksel Bothner-By and, later, John Baldeschwieler.

Mostly, we tried to develop new applications to chemistry and extend old ones, which was relatively easy to do in those days. Chemists knew little of the physics of NMR, and the physicists had no idea of what chemists were interested in. By being somewhere in between, I could see new possibilities. (An advantage of being between fields is that it is easy to fool the specialists in one of them into thinking you know a lot about the other.) Among other things we worked on chemical shifts from aromatic ring currents,³ rapidly rearranging molecules,⁴ methods for analyzing high-resolution spectra,⁵ phase transitions in solids,⁶ self-diffusion and relaxation in liquids,⁷ electric field effects,⁸ and relaxation in gases and intermolecular forces.⁹ Some of these researches led to forays into other techniques, such as the Mössbauer effect and the Kerr effect in nonideal gases,¹⁰ and we introduced the Avis as the standard unit of angular frequency.

In 1962 I was given a Guggenheim Fellowship which allowed me to take a year's sabbatical leave. I spent the first part in Moscow under the first Interacademy Exchange Agreement. On the way over I visited Ionel Solomon in Paris. He gave me a preprint of his work with Ezratty¹¹ and awoke my interest in strong rf fields, which I had theretofore avoided because of my difficulty in understanding Redfield's classic paper.¹² I soon had the opportunity to discuss all this with Boris Provotorov, whose approach I found even more impenetrable. (I am grateful to Maurice Goldman¹³ for clarifying much of this subject matter later.) On the whole, my stay in Moscow was more a sociological and linguistic than a scientific experience, although it led to a number of friendships and some years later to a lecture tour and a book.¹⁴ The following fall I insinuated myself into Erwin Hahn's lab in Berkeley. The Hartmann-Hahn effect had been published the previous year,¹⁵ Dick Slusher, Russ Walstedt, and Gil Leppelmeier were still there pursuing its corollaries, and I shared an office with Jack Butterworth, who was visiting from Harwell. I learned to become much more at ease with the theory of spin dynamics in solids, and was enormously stimulated by Hahn and by the atmosphere and spirit of his group.

COHERENT AVERAGING: 1965–82

For a few years before and after my stay in Berkeley I was a consultant to Harvey-Wells, Inc., later Magnion Inc., a manufacturer of electromagnets and NMR gaussmeters. Existing commercial NMR spectrometers were of the CW variety, and Ed Ostroff, the Engineering V.P., saw an opportunity to develop a pulsed spectrometer to satisfy increasing interest in that area. His apparatus was the first which could generate long pulse trains, with limited phase control, and at the same time had the high transmitter power and rapid recovery needed for FIDs in solids. Testing an early machine in the spring of 1965, Ostroff chanced to apply a Carr-Purcell (CPMG) sequence to a solid, and was astonished to see a long train of echoes—up to thousands of them as the pulse spacing τ was decreased. I was equally surprised, but as the consultant I was supposed to explain the effect. In further experiments we found that the phase shift of the initial pulse

was essential, and that the refocusing pulses had to have a flip angle of less than the canonical 180° ; 90° seemed much better.

Under these conditions the first echo had to be Jack Powles's 'solid echo', but the theory of that effect¹⁶ gave no reason to expect long trains such as Ostroff saw. The intensity of the solid echo is given by

$$\langle \hat{I}_x(2\tau) \rangle = \langle \hat{U}(2\tau) \hat{I}_x \hat{U}(2\tau) \rangle \quad (1)$$

$$\hat{U}(2\tau) = \exp(-i\hat{\mathcal{H}}\tau) \exp\left(-i\frac{\pi}{2}\hat{I}_x\right) \exp(-i\hat{\mathcal{H}}\tau) \quad (2)$$

The result can be calculated by writing the dipole-dipole Hamiltonian $\hat{\mathcal{H}}$ in spin operators, expanding the propagator $\exp(-i\hat{\mathcal{H}}\tau)$ in a power series, performing the indicated pulse rotation, collecting terms, and taking the trace. In this way it is found that the decay at time 2τ , which would be of order $M_2\tau^2$ in the FID, is canceled in the echo, the leading term now being of order $M_4'\tau^4$. (Here M_2 is the Van Vleck second moment, and M_4' is a modified fourth moment.) I simply extended the calculation to the second echo at time 4τ and found a cancellation of the τ^4 terms, leaving a decay of order $M_6'\tau^6$ and predicting the second echo to be stronger than the first (as we in fact verified experimentally). The method of calculation did not easily lend itself to extension to later echoes, so I punted by fitting the experimentally observed exponential decay to the rough calculation for the second echo, in the spirit of Boltzmann's molecular chaos assumption. This seemed to give qualitative agreement with experiment and we published a Letter¹⁷ which also contained an alternative interpretation in terms of spin locking. Jim Wang later fleshed out both approaches.¹⁸

The Fourier transform relationship between FIDs and spectra was well known at that time¹⁹ as was the notion of sampled signals and discrete FTs, and it was natural to think of lengthened decays as somehow corresponding to sharpened spectral lines. From this point of view it was easy to think of the *envelope* of a Carr-Purcell echo train as equivalent to the sampled FID of a system whose inhomogeneous broadening had been artificially suppressed. Extending this logic to Ostroff's pulse sequence (nowadays OW-4 in conventional nomenclature), it seemed that the homogeneous dipole-dipole broadening had been removed. That broadening was generally considered to be a nuisance by chemists, since it concealed the small chemical shifts that they love so well and prevented the widespread use of NMR spectroscopy in solids. Actually the chemical shifts were suppressed, too: an explicit calculation in the style of equations (1) and (2) showed that the inhomogeneous terms refocus on every fourth echo. Nevertheless I wondered whether some other sequence could be found which would remove the dipole-dipole broadening *selectively*.

A somewhat innocent first attempt was based on the obvious fact that the refocusing of inhomogeneous decay could be defeated by alternating the carrier phases of alternate 90° pulses, whereas a pure dipolar decay would not be affected. Lee Huber modified our Magnion spectrometer to try this. When the transmitter was shifted slightly off-resonance the new sequence showed the expected oscillation,²⁰ but it damped rather quickly. The reason was clear from a calculation including *both* dipole-dipole and shift contributions; cross

terms between them led to damping in about the time it took the shift to exhibit itself, i.e. the dipolar broadening could be reduced only just sufficiently to uncover the largest chemical shift present in the sample.

Lee Huber and I had many conversations trying to see what was wrong and whether our goal could be reached in some other way. We were joined by other members of the group, including David Ellett, Jim Wang, and subsequently Bob Vold. (Bob stimulated the 2D inversion–recovery FT method for measuring T_1 s of multiple lines.²¹) In the end I made the most progress while I was away on an extended European trip during the summer of 1967 and thinking intensely about the problem. Several critical insights gradually emerged (though not as neatly as the following would suggest):

- The long decays of OW-4 and WH-2 really resulted not from an annihilation of interactions but rather from a kind of spin locking. To get at the desired result we needed to concentrate on the propagator U [equation (2)], not on particular initial states and observables [equation (1)].
- For *cyclic* sequences the propagator [equation (2)] could be written in a *toggle frame*, in which the pulses disappeared and what was left looked like the result of a time-dependent Hamiltonian $\hat{H}(t)$, periodic *modulo* the cycle time t_c .
- The cycle propagator, being unitary, could be expressed as a function of a Hermitian operator: $\hat{U}(t_c) = \exp(i\hat{A})$, and by writing $\hat{A} = -\hat{H}t_c$ one saw that $\hat{H}(t)$ could be replaced by the *time-independent* Hamiltonian $\hat{H}$. The signal during the pulse train was identical to the FID which would result from a spin system with Hamiltonian $\hat{H}$ if both were sampled at the same interval t_c . I did not see how to construct $\hat{H}$ in general, but to lowest order it was just a time average of $\hat{H}(t)$ over the cycle.

The goal remained to design a pulse sequence that would remove dipole–dipole couplings and retain chemical shifts. In hindsight this should have been easy, but in fact I had no idea whether it was even possible. Suddenly one fall morning at breakfast the solution came to me in a rush. Within a few minutes the WAHUA sequence (now called WHH-4 in East German parlance), its scaling factor and timing variants, its relationship to the magic angle and the Lee–Goldburg experiment,²² etc. were all obvious. (I am thankful that Walter Goldburg, not being a chemist, never thought about chemical shifts.) I rushed to the lab in great excitement. Wang, Huber, Vold, and I shortly had a series of intense discussions which refined and extended the general ideas and suggested a number of interesting applications. We still did not know how to calculate the higher order corrections to the average Hamiltonian, although we were able to come up with a somewhat tortured discussion of the requirements for validity of the lowest term. We wrote a paper²³ about all this while Lee Huber began modifying an old Varian spectrometer to provide high-powered pulses of the four phases needed for the new sequences. I was once asked whether I had not been guided by some ‘arm waving’ physical picture, *a la* Hahn, rather than just algebra. I responded that since I was dealing with an essentially many-body problem, I would, like some Hindu deity, need Avagadro’s number of arms.

Ulrich Haeberlen arrived from Germany during this time. He knew of the Magnus expansion and showed us how to put the average Hamiltonian on a sounder theoretical basis, to take into account the finite strength of the rf field, etc.

He confessed later that he was less sanguine than I about the convergence of the Magnus Hamiltonian under practical experimental conditions. He was also a superb experimenter, and played a major role in the design of that spectrometer and subsequent ones. He remains to this day the ultimate practitioner of multiple pulse NMR, and what is now known about chemical shielding tensors of protons is owed completely to his insight and persistence.

The first experiment was done on the ^{19}F resonance of a sample composed of a small chip of doped CaF_2 and a drop of liquid $\text{C}_6\text{H}_5\text{CF}_3$. All observations were made directly on an oscilloscope. The normal FID showed an initial rapid transient due to the solid, followed by a very long signal from the liquid, which we made oscillatory by setting the magnet a bit off-resonance. When the multiple pulse train was applied, the transmitter pulses drove the scope off-scale, but in the windows between pulses we could see short segments of interleaved free precession signals that showed a complex beating structure. We were sure that this was the expected decay of two narrow resolved signals, one of them from the CaF_2 . To make a convincing case for publication, we needed a Fourier transform but we did not have a transient recorder or computer. Lee measured the signals from a scope photograph and calculated the Fourier transform manually.²⁴

Armed with Haeberlen’s definitive basic theory of the average Hamiltonian and its applications,²⁵ we demonstrated experimentally some of the ideas we had about the scaling of chemical shifts,²⁶ and chemical shift anisotropy,²⁷ and we set about building a more powerful and versatile spectrometer.²⁸ During this period we bought a signal averager and PDP-8 and PDP-12 computers. Michael Mehring and Bob Griffin joined the group and, with Dave Ellett, provided a major stimulus for further development of multiple pulse ideas and did the first definitive measurements of chemical shielding tensors.²⁹

We could have gone on to improve our multiple pulse methods, but it was clear that the general approach of average Hamiltonians had many other possibilities. In principle, the Hamiltonian of a system did not have to be accepted as Nature provided it, but could be transmuted at will into a perhaps more useful form by the experimenter, a sort of alchemist whose philosopher’s stone was a pulse sequence. We proceeded to fit known experiments into this unconventional viewpoint and to invent new ones:

- Won-Kyu Rhim and Alex Pines used the new apparatus to explore the idea, originated by Rhim and Kessemeier,³⁰ of generating a pulse sequence for which the average dipole–dipole Hamiltonian would reverse in sign, thus generating an apparent backward time development of the spin system. This sequence was used to generate an essentially perfect (‘magic sandwich’) echo in a homogeneously broadened solid after the initial FID had effectively disappeared. This experiment generated a great deal of interest, since it had been a part of the lore of spin physics that the dipolar FID was a thermodynamically irreversible process. In fact our Letter to the Editor³¹ was initially rejected by a referee who, despite our derivation, thought that what we claimed was impossible.
- The Hartmann–Hahn experiment was not useful for resolving narrow lines in, for example, ^{13}C spectra, because the spectrum obtained was in effect lifetime-broadened by the very coupling which made it possible. Alex Pines conceived

the notion of dividing the experiment into two stages governed by different average Hamiltonians. In the first, the rare spins were polarized by the Hartmann–Hahn procedure. We called this CP for ‘cross polarization’, to emphasize that we were interested in polarizing the rare (*S*) spins rather than depolarizing the abundant (*I*) ones. (This is the Saclay convention: Hahn called them I_b and I_a , possibly for ‘bundant’ and ‘abundant’.) In the second part, the carbon irradiation was turned off and the new average Hamiltonian, whose FID was recorded, corresponded to a ^{13}C system developing under chemical shifts and decoupled from all protons. This very simple proton-enhanced NMR experiment was demonstrated by Pines and Gibby;³² my principal contribution was in persuading Pines (never an easy task) that he should use CW rather than pulsed rf fields.

- Like Hartmann and Hahn, we had used thermodynamics in the rotating frame³³ to predict the asymptotic magnetizations in the CP process, but it was clear that the transient behavior during approach to quasi equilibrium spoke of the details of the interaction between a rare spin and its neighbors. During a year in our laboratory, Dan Demco had worked out a memory function theory³⁴ applicable to CaF_2 , and had ‘explained’ the very surprising correlation function observed in CaF_2 by McArthur, Hahn, and Walstedt.³⁵ I was more interested in the situation in organic solids, where a ^{13}C spin interacted mainly with only one or two proton neighbors. As Ernst’s group had shown,³⁶ its magnetization displayed an oscillatory transient behavior from which internuclear geometries could be calculated. We developed a 2D method which added multiple pulse irradiation of the protons or spin locking at the magic angle. The experiment worked,³⁷ but was mainly useful in suggesting a simpler scheme which we called separated local field (SLF) spectroscopy.³⁸
- It was appealing to think of removing the powder broadening found in multiple-pulse and CP/decoupling spectra by adding magic angle sample spinning, another form of alchemy discovered by Raymond Andrew³⁹ and Irving Lowe.⁴⁰ I borrowed a spinner from Jim Carolan, who had been Andrew’s student, and set Stefan Pausak to building one suitable for our use. However I attached a low priority to this task, since I was worried that the spinning, like random molecular motion, would interfere with the narrowing caused by the rf.⁴¹ In this I was too sophisticated for my own good: Soon Ed Stejskal and Jake Schaefer, unafraid of such bugaboos, demonstrated the remarkable power of CP MAS. CRAMPS, the corresponding emendation of multiple-pulse NMR, suffers much more from the interferences that bothered me. Lippmaa’s group in Tallinn recognized that the special success of CP MAS depends on the inhomogeneous nature of the chemical shift broadening. Matti Maricq carried out an extensive analysis of the consequences of this fact with many experimental illustrations.⁴² Subsequently we explained the interferences between spinning and cross polarization,⁴³ and showed ways in which interferences could be used to study slow molecular motions.⁴⁴

HETERONUCLEAR DECOUPLING IN LIQUIDS: 1980–82

Chemists began to give increased attention to spin decoupling as magnets became stronger. In ^{13}C spectra, in particular,

the power needed to decouple protons throughout their increasing range of chemical shifts became uncomfortably large. Many schemes for broadening the bandwidth by modulating the decoupling transmitter were proposed: the most widely used was Ernst’s quasirandom ‘noise modulation’.⁴⁵ The idea, seductive but entirely wrong, seems to have been that each sideband would somehow decouple whatever spectral line was closest to it. The new schemes all tended to give some modest improvement over CW decoupling, but it seemed that no further dramatic advances were possible or they would have been found by accident. I gave a talk at an ENC conference in which I discussed approaches to the problem from the average Hamiltonian point of view, and was rash enough to ‘show’ that the limit of possibilities had already been substantially realized. Ray Freeman was in the audience and evidently took this as a challenge. A year or two later he showed experimental results that were enormously better than anyone had previously seen, but wouldn’t say how he had done it. I, in turn, took this as a challenge and went back to reexamine the underlying theory—of course with the advantage of knowing that I must have overlooked something important.

After some false starts based on average Hamiltonians, I found a very simple theory which concentrates on what happens to the proton *I*, not the ^{13}C , during the decoupling sequence. For rf irradiation of phase ϕ , a proton shifted by Δ from the transmitter undergoes a classical precession about a field whose components are:

$$\mathbf{B}_{\text{eff}} = B_1(I_x \cos \phi \mathbf{i} + I_y \sin \phi \Delta \mathbf{j}) + \Delta I_z \mathbf{k}; \quad \Delta = \delta \pm J/2 \quad (3)$$

As the rf parameters cycle through a series of values, the proton accumulates a net rotation *R* which is the product of the individual precessions. If *R* can be made independent of variations in δ , it is as if the proton ‘doesn’t know about’ the term in *J*. Since coupling is reflexive, the carbon does not know about the proton either. The quality of any decoupling sequence is then analyzed by computing the range of δ over which *R* does not change locally by more than some agreed upon amount. If one starts with a simple sequence for which *R* is approximately zero for small δ , it is possible to find iterative schemes for building up longer sequences with better and better properties.⁴⁶ I worked out various examples, but Freeman won by constructing some others, e.g. WALTZ, which were superior to the ones I had thought of.

NMR AT LOW TEMPERATURES: 1983–93

A remarkable discovery by Friedman, Millet, and Richardson⁴⁷ seemed to me to offer a possible basis for a general method of increasing the sensitivity of NMR by several orders of magnitude. I persuaded the NSF to give me a supplemental grant to buy a dilution refrigerator. I also took on two talented postdocs, Philip Kuhns and Chris Hammel. Hammel brought from the Richardson group at Cornell the knowledge of cryogenics which I lacked. After he went to Los Alamos, Oded Gonen enthusiastically filled the gap he left. We spent more than a year working with Oxford Instruments Ltd. to design a refrigerator with the unusual features needed for ‘routine’ NMR and an NMR probe to mate with it.⁴⁸

Once the machine was working, we decided to make our first major experiment a measurement of spin diffusion in CaF_2 . For various reasons deriving from its slowness ($D \sim 10^{-12}$ cgs), no reliable measurement had been made of this quite fundamental and theoretically interesting transport phenomenon. My notion was to follow the total magnetization (initially saturated) in single crystal plates of CaF_2 immersed in ^3He . The low temperature would provide a large source magnetization at the surface, and the absence of bulk relaxation would allow the long runs needed to cross over to the asymptotic $t^{1/2}$ dependence expected for diffusion-limited growth.

The results didn't fit. Ultimately Phil Kuhns persuaded us that in fact we were observing bulk relaxation, at a rate 10^9 faster than anticipated! The next step was to measure T_1 and determine its dependence on the available parameters B_0 and T . This required enormous patience, inasmuch as T_1 was sometimes as long as several months. In the end Hammel found that the results accurately obeyed the relation $T_1 \propto \exp [c(B_0/T)^{1/4}]$,⁴⁹ a dependence which has still not been theoretically understood. Subsequently Charlie Slichter made a suggestion that led to at least a qualitative insight and a joint publication.⁵⁰

I had hoped that well-resolved powder spectra could be routinely obtained, and the resulting chemical shift tensor elements interpreted in terms of electronic structure and chemical bonding. This seemed especially attractive for molecules adsorbed on surfaces, for which the high sensitivity would be extremely important. Unfortunately, it turned out that most such systems displayed a very large amount of inhomogeneous broadening. I believe this must arise from small contaminations with paramagnetic impurities: their local fields average out at higher temperatures through rapid electronic relaxation, but become static much below 1 K because the electronic spins become completely polarized. Thus most of the discoveries we made in millikelvin NMR were interesting academic curiosities rather than foundations of a new technology.⁵¹

COMPUTER EXPERIMENTS: 1985–94

The failure of our experiment on spin diffusion led me to wonder whether it could be replaced by a computer experiment, in the style of molecular dynamics. At first sight, the flip-flops of neighboring spin- $\frac{1}{2}$ nuclei seemed very quantum mechanical. Because local coherent behavior gives way to apparently dissipative effects only at large distances and times, such a calculation would require diagonalization of matrices of dimension perhaps 10^4 and would be hopeless. However it was clear that the diffusion effect, like most physical processes is not *essentially* quantum in nature, and would exhibit itself in qualitatively the same way for classical gyromagnets. It was even possible to convince oneself, on the basis of the theory of moments,⁵² that the correspondence might be semiquantitative. Armed with this encouragement, Changguo Tang undertook a purely classical calculation of diffusion of Zeeman and dipole–dipole energy in crystals. The results were in good agreement with previous approximate theories, and were extended to plausible predictions of effects which have not yet been measured.⁵³ In a completely independent exercise, my troublesome colleague deBouregas has created and distributed a computer program which is

useful for making exact quantum mechanical simulations of a great variety of magnetic resonance experiments, practical and hypothetical.⁵⁴

Weaver, Harry E.: Historical Comments on the Early Years of Superconducting NMR

Harry E. Weaver

Portola Valley, CA, USA

EARLY 1960S: THE START

On my return to California and the Instrument Division of Varian Associates from a leave of absence of two years as Instructor in the Physics Department of the University of Zürich, Switzerland, the superconducting properties of the alloys of niobium were appearing in the literature. The relatively high transition temperature (relative to 4.3 K), and the tolerance of high magnetic fields (in excess of 70 kG) while maintaining the superconductive state in the alloys, suggested that wires made from these materials might be wound into solenoids to produce fields useful for NMR, especially for high-resolution analytical NMR. If such fields could be made sufficiently homogeneous and stable with time to match or exceed the existing properties routinely available from iron core electromagnets of commercial instruments (operating at 100 MHz for protons), then such an advance would be of great significance and commercial value! At the time, neither of these questions had definitive answers. The high-field properties had been established early on, but the extraordinary requirements of homogeneity over the sample volume and corresponding time stability required measurements by high-resolution NMR **itself** to establish.

A modest program under my direction was started at Varian with the encouragement and support of Dr. Martin Packard, then Director of Research of the Instrument Division at Varian.

SHORT SAMPLE TESTS

Kilometer lengths of the superconducting alloys were not yet easily available at the start of the program, so we began with testing short samples (a few cm) cut from what lengths we could obtain. These samples were mounted in the bore of very small solenoids wound with copper wire which when immersed in liquid helium could be pulsed to a calculated field well in excess of the published critical field (order of 80–100 kG). In this way we could obtain experience measuring these alloys (NbZr and NbTi) as well as with handling liquid helium, for none of us had had any significant experience in obtaining, transporting, storing, or transferring the cryogen from a purchased 25 L storage Dewar to our experimental setup. In fact, helium liquifiers were fairly rare and those present in the immediate area were not easily available to an industrial laboratory. As it turned out, through a personal contact, we could obtain, on a one-time basis, 25 L of liquid from the ADL liquifier at the Naval Post Graduate

School in Monterey, CA, providing I supplied the compressed gas necessary to obtain 25 L plus any losses. This liquifier was located some two hours drive from Palo Alto and Varian. Thus, we loaded up a pickup with the necessary number of heavy cylinders, drove to Monterey (no freeways then) with our precooled (with LN₂) helium Dewar and spent the day plumbed to their machine. We kept our fingers crossed that no plugs would form from possible trace impurities in our gas and that the liquefaction rate would be maintained!!

The liquefaction went remarkably well, but the drive back to Palo Alto with the empty cylinders and Dewar full of cryogens (LHe and LN₂) was an anxious one in our naive state as we had no experience to fall back on as regards what to expect of the effect of jostling from the roadway on the liquid helium and what that action would cost us in terms of evaporation, or whether we were running a significant risk of forming a frozen air plug in the helium Dewar vent tube. (In those days, check valves were homemade and primitive, but ours proved to be effective.) Once we had the liquid available, we could then test our home-constructed vacuum-jacketed transfer line formed from thin-wall stainless-steel tubing and bent in the form of a large U, the ends of which were welded and the concentricity maintained by a number of thin Teflon three-point ‘stars’ spaced at intervals along the inner tube; any thermal shorts would mean immediate loss of the liquid phase during transfer!! The entire system of evacuated transfer line and nested experimental Dewars containing the material to be tested, leads, and support tubes could not be tested until we had our few liters of helium!! Economy of liquid was uppermost in our minds. It was with this system of nested glass Dewars, immersed pulsed coils, leads, and supports that we were able to verify successfully the short-sample published data of the niobium alloys.

With these data behind us and having eventually solved the liquid helium supply limitation, we were able to push on to the heart of the program, viz. the design, construction, and testing of large-bore solenoids; i.e. large enough for serious high-resolution NMR studies of the solenoidal magnetic fields with the sample at room temperature.

SOLENOIDS, TRAINING EFFECTS AND FLUX TRAPPING IN TYPE II SUPERCONDUCTORS

The first kilometer lengths of niobium alloys were drawn bare without a cladding of copper or insulation, as the techniques for the drawing of clad niobium alloy wire were still in the experimental stages. Hence, our first SC solenoids using bare wire were small bore, but these did provide good vehicles for the design and testing of superconducting/normal state switches. These switches when heated above T_c allowed energizing of the solenoids and, when the heater to the shunting switch was turned off, permitted preliminary studies of the persistent mode. It was with these small solenoids that we first encountered the phenomenon of ‘training’, viz. successive quenching from the superconducting to the normal state during the energizing to ever higher currents, ultimately ‘topping out’ at the design current and field. That a solenoid would ‘remember’ the previous quenches despite the fact that the energy ‘dump’ was enough to carry the bulk of the wires to a temperature well above T_c was always a puzzle to us.

As the solenoids became larger and larger with corresponding higher L/r , or time constants, it became abundantly clear that the copper-clad wires had to be coated with insulation to avoid the excessively long time constants. Interlayers of copper shim stock were used in an attempt to ensure as good a thermal conductivity to the helium bath as possible at the cost of a smaller fill-factor of the windings. A less efficient (in terms of number of turns of wire) but more stable solenoid operation resulted.

PERSISTENT MODE AND FIELD HOMOGENEITY

Conventional wisdom in those days held that flux trapping and even quenching cycles would frustrate attempts to achieve homogeneous magnetic fields in the region of the sample probe. We proposed using gradient trim-coils wound on forms positioned outside the bulk of the main solenoid. Hence, it would be necessary for the field lines from these coils to penetrate the bulk of the superconductor main coil in a predictable manner. Our experience with the behavior of ferromagnetic domains of iron magnets, and their effect on the field in the gap between pole pieces, suggested that a strong parallel might exist between the behavior of trapped flux domains in Type II superconductors with that of the domains of iron pole pieces. Accordingly, we designed gradient cancelling coils to handle the first-order gradients. These consisted initially of over-wound end sections for the axial gradients and two sets of transverse gradient coils to remove the transverse gradients; each set of coils possessed their individual S/C switches. Thus, with the combined use of these coils, the central field could be 'domed' or 'dished', the transverse gradients cancelled, and the field made uniform to a very high degree as measured by the NMR signal. Any residual nonuniformities introduced by the probe itself could be handled by the conventional room-temperature trim coils mounted on the NMR probe.

With the homogeneity of the central field under control, small time-dependent shifts in the field could then be studied, sometimes upward and sometimes downward, depending upon the precise form of energizing current from the programmed power supplies during energizing of a solenoid for the first time after a cool-down. Magnetic perturbations from outside the Dewar would also cause minor shifts in the central field and its gradients, but these effects could be held at a minimum through proper current programming and choice of environment. **No long-term decay of the persistent current was ever observed.** (It should be noted, however, that a superconducting solenoid is a **flux conserver not a flux density, or field, conserver!**) Thus, to our great pleasure and

excitement, once the solenoid and its shim coils were placed in the persistent mode and the system of coils removed from the external power supplies, the field and its distribution over the sample appeared to be preserved indefinitely.

THE FIRST SUPERCONDUCTIVE NMR RESEARCH SPECTROMETER

The first complete prototype NMR spectrometer employing a high-field high-homogeneity superconductive solenoid, with associated Dewar and controls operated at 200 MHz for ^1H NMR. It was exhibited to a group of invited analytical chemists at a Pittsburgh Conference in a room at the William Penn Hotel in Pittsburgh (I slept in the same room with the instrument!). It was extremely well received!! This instrument was delivered after the end of the conference to members of the DuPont Experimental Station in Wilmington for field evaluation. Their evaluations formed an important basis for ongoing improvements of the commercial model under construction which was to be subsequently delivered to their laboratory. That first commercial instrument, with subsequent additions to its capability of excitation and detection of proton NMR with the addition of Fourier transform signal-enhancement sections, performed for many years and was retired only a few years ago (along with the technician originally assigned to operate it as a service to the research staff)!! That instrument was indeed a major advance and 'path-finder' for the modern instrument and I don't believe one would find today any analytical chemical laboratory without an NMR spectrometer and associated high-field superconducting solenoid. At many institutions today, multinuclear, Fourier transform instruments are commonplace and are so complex that a trained specialist is needed to operate them. Time on the instruments of today is so tightly scheduled that a student usually only rarely has an opportunity to receive hands-on experience, except possibly during a special well-supervised course on its use!!

Webb, Graham A.: My Developing Interest in NMR Spectroscopy

Graham A. Webb

University of Surrey, Guildford, UK

It all began during the final year of my undergraduate course at Bristol, during the academic year 1959–60. There were lectures on molecular structure determination which included an introduction to the relatively new technique of ^1H NMR spectroscopy. The power of the method was very appealing and retained my interest when, in 1960, I went to University College, London to start my Ph.D. research on the measurement and interpretation of variable temperature magnetic susceptibilities of transition metal complexes. In the laboratory next to the one I was working in I saw my first NMR spectrometer. It was being used for ^{13}C , ^{14}N , and ^{17}O NMR measurements by Dick Bramley and Garth Kidd; through them I was introduced to heteronuclear NMR studies and all the problems that studying these nuclei on a 40 MHz CW instrument entailed.

Unfortunately it was not possible to obtain funds to study NMR during my postdoctoral year at UCL (1963–64), so I tried the next best thing, namely ESR of iron(III) complexes. Following this, I was appointed to a lectureship in chemical physics at Surrey University, which found me in charge of a 60 MHz spectrometer and the responsibility of ensuring that the practical chemists had a routine ^1H service. Following the ESR work at UCL I was fascinated by the prospect of investigating the NMR spectra of paramagnetic complexes; fortunately my first Ph.D. student, Colin Honeybourne, was well motivated, so together we set out to look at contact and dipolar interactions of paramagnetic systems by means of ^1H NMR. At the time, Jim Feeney was working in the nearby Varian laboratory and he very generously helped us by providing access to an HA-100 instrument, which we eventually purchased. The work on paramagnetic systems generated an interest in the theory of chemical shifts on paramagnetic and diamagnetic compounds which was enhanced when, in 1966, I had the opportunity to visit Michal Witanowski and Lech Stefaniak at the Institute of Organic Chemistry of The Polish Academy of Sciences, and to perform some ^{14}N NMR measurements. The large range of chemical shifts which we observed required some theoretical explanations. Fortunately, at Surrey I was able to attract a number of students in the 1970s who had an interest in theoretical chemistry, in particular Kais Ebraheem and Mehdi Jellali-Heravi, and we developed Pople's shielding model to include INDO/S parameterization and nonspecific solute–solvent interactions via the Solvaton model to provide an account of the nitrogen chemical shifts, as well as those of some other first and second row nuclei.

In 1973, Michal Witanowski and I coedited the first book on nitrogen NMR; one of our contributors was Ted Axenrod from City University, New York, who was very interested in ^{15}N – ^{15}N spin–spin couplings and persuaded me to become interested in the theory of these, rather

unusual, data. Consequently, we developed at Surrey a series of semiempirical MO calculations of spin–spin couplings. The majority of this work was carried out by two Ph.D. students, Tun Khin and Sangwahn Duangthai, and provided an explanation for many of the heteronuclear coupling data appearing in the literature at that time. This work was also extended to include nonspecific solute–solvent interactions by means of the Solvaton model.

My first visit to Japan was in 1978 when I had the great pleasure of meeting Isao Ando at Tokyo Institute of Technology. Like us at Surrey, Isao and his students had a great interest in nuclear shielding calculations including solvent effects. Jointly we developed the Solvaton model further and applied it, with success, to a number of nuclei. In addition to the effects of solvent on chemical shifts and spin–spin couplings, we established an interest in the influence of pressure on NMR parameters and jointly carried out measurements and calculations which helped to explain the observed effects. Our collaboration resulted in the book entitled 'Theory of NMR Parameters' in 1983 which dealt with the current situation regarding calculations of chemical shifts and spin–spin couplings. Our joint interest in the theoretical aspects of chemical shifts has continued and resulted, in 1992 and 1993, in our first papers dealing with *ab initio* MO calculations of nuclear shieldings using the GIAO procedure. Another aspect of our cooperative research has been in solid state CP MAS measurements of ^{13}C and ^{15}N NMR spectra. A particular area of joint interest has been in the ^{15}N solid state NMR spectra of peptides and polypeptides, and we published a joint review of this work in 1993.

The cooperation with my Polish co-workers is still continuing apace. We have now produced five monographs on nitrogen NMR and another one is in the planning stage. Our joint research activities have tended to concentrate on a study of both specific and nonspecific solute–solvent effects on nitrogen shieldings, treated both experimentally and theoretically, and on multinuclear MR studies of various equilibria and structural properties of molecules both in solution and in the solid state. The importance of making available and reading reviews on current research areas was apparent from my early days as a research student. Consequently, when the opportunity arose in 1975 to take over from Eric Mooney as editor of 'Annual Reports on NMR Spectroscopy', I felt this to be a task which could be of use to the NMR community and I took it on in the hope that I could continue to attract reviews of an acceptable quality. Thanks to the generosity of a number of leading NMR spectroscopists in providing their time and knowledge, my anticipations have not been frustrated. Similar motives lay behind my acceptance, in 1977, of the editorship of 'Specialist Periodical Reports on NMR' which had been successfully launched by Robin Harris and continued by Ray Abraham. Due to the dedication of the contributors, this series has also continued to flourish.

A more recent development is in NMR studies of food constituents. This is involving us in multidimensional NMR measurements on food peptides and *ab initio* MO calculations of the ^{13}C shieldings of polysaccharides. In 1992 we held the first International Conference on Applications of Magnetic Resonance to Food Science at Surrey, which proved to be sufficiently successful for the second conference to be held in Aveiro, Portugal, in September 1994, and the third to be planned for Nantes, France in September 1996.

Biographical Sketch

G. A. Webb. *b* 1935. B.Sc., Ph.D., D.Sc., 1974, University of London. Successively lecturer, 1964, senior lecturer in chemical physics, 1975, reader, 1985, and professor in chemistry, 1995, at the University of

Surrey. Approx. 320 publications and about 50 edited volumes on NMR. Research interests include a study of solute–solvent interactions by nitrogen NMR, solution and solid state NMR studies of molecular structure, theoretical aspects of nuclear shielding and of drug–receptor interactions.

Wehrli, Felix W.: From Carbon-13 to Quadrupolar Nuclei NMR and Medical Imaging—Reflections

Felix W. Wehrli

University of Pennsylvania Medical Center, Philadelphia, PA, USA

CARBON-13: FROM INDIRECT DETECTION TO ROUTINE STRUCTURE ANALYSIS

We owe the continued progress of NMR from a physics curiosity to what promises to become the preeminent medical imaging modality of the 21st Century to the ingenuity and tenacity of the many pioneers whose work is commemorated in the eight volumes of this Encyclopedia. Many of today's capabilities have long been taken for granted by the younger generation of spectroscopists and chemists. A case in point is natural-abundance carbon-13 spectroscopy, part of the development of which I had the good fortune to witness, though much more from the perspective of user than innovator.

My fascination with NMR—undiminished up to the present day—began in earnest in 1965 during a graduate course on instrumental analysis, taught by Professor W. Simon at the Swiss Federal Institute of Technology (ETH). It was the high time of proton NMR, the era of the Varian A-60, the first mass-produced NMR spectrometer which led the diffusion of high-resolution NMR into analytical organic chemistry. In searching for a thesis subject two years later, Simon told me that he thought carbon-13 NMR had, because of its much larger chemical shift range and already proven sensitivity to stereochemistry, even greater potential. I was rapidly convinced after reading David Grant's and Jack Roberts's work in which they showed that separate chemically shifted resonances could be observed for virtually all carbons in molecules as complicated as steroids.

All of this work would, of course, have been impossible without proton noise decoupling, first conceived by Richard Ernst in 1966,¹ enhancing the signal-to-noise ratio at least 10-fold and greatly simplifying the spectra (albeit at a considerable loss in information). I became painfully aware of the critical role of proton noise decoupling during my early attempts to generate natural-abundance ^{13}C NMR spectra on the Bruker-Spectrospin HFX-10 multinuclear spectrometer, purchased by the department specifically for this project. The lack of this capability during the entire period of my dissertation was exacerbated by poor magnetic field homogeneity, which made detection of natural-abundance ^{13}C in large sample tubes virtually impossible, forcing me to resort to 5 mm samples for which the field could be adequately shimmed. Further, pulse Fourier transform techniques, though first described in 1966,² were not generally available before about 1970. Hence, I had a two orders of magnitude sensitivity problem!

Unwilling to give up, I thought about ways around this problem. In this effort I came across a paper by Baker in which he succeeded in obtaining a high-resolution spectrum of trifluoroacetic acid by heteronuclear INDOR spectroscopy, achieved by monitoring a carbon-13 satellite in the ^{19}F spectrum while slowly sweeping across the ^{13}C resonance.³ Since the signal-to-noise ratio (SNR) scales as γ^3 , detection of the proton resonance of a nucleus spin-coupled to ^{13}C could be detected with 64-fold increase in sensitivity relative to direct detection. If the proton resonance is saturated, transient nutations are induced and the signal amplitudes can be predicted on the basis of the resultant population redistribution, using the arguments underlying the generalized Overhauser effect. The approach was, of course, limited to those cases where a ^{13}C satellite could be observed, which required sufficiently large coupling constants and fairly high sample concentration. In practice, the method was confined to the detection of methyl carbon resonances. An example is given in Figure 1. Nevertheless, I succeeded in measuring the methyl carbon shifts in a great many compounds and studied substituent effects on ^{13}C shieldings and ^{13}C – ^1H coupling constants.

As a whole, however, this work had little impact on the subsequent evolution of ^{13}C NMR spectroscopy, and it served merely as a stimulus for future work. In truth, the methodology was, at the time, already outmoded as a result of the anticipated availability of pulse Fourier transform ^{13}C spectroscopy with proton noise and coherent off-resonance decoupling.

The commercialization of multinuclear high-resolution pulse Fourier transform MR in the early 1970s by Varian, Bruker, and JEOL gave ^{13}C MR an unprecedented impetus in that it rapidly turned into a standard analytical tool in the organic chemistry research laboratory, providing a powerful complement to proton spectroscopy. Next to the previously mentioned milestones—pulse FT techniques and broadband proton decoupling—the course of developments was largely spurred by another event, the emergence of the minicomputer as an integral subsystem of the spectrometer rather than just

Figure 1 Transient nutations of the high-frequency ^{13}C satellite of the isotopomer $^{13}\text{CH}_3\ ^{12}\text{CN}$ at natural abundance, obtained at a ^{13}C sweep rate $\text{d}\nu_2/\text{d}t = 4.8\text{ Hz s}^{-1}$ and $\gamma B_1/2\pi = 0.67\text{ Hz}$ for the proton rf field at 90 MHz. (Taken from Ref. 4 with permission)

an add-on. While ^1H NMR of organic molecules was conveniently achieved in the continuous-wave (CW) mode, CW carbon NMR, in spite of noise decoupling and signal averaging, was quite impractical for all but the most skillful experimenters and demanded scan times in excess of 1 h on 1 mol solutions. In fact, only a few ‘masters of the art’ succeeded in acquiring and analyzing ^{13}C spectra of molecules >1000 Da. One of them was Leroy Johnson, then at Varian, who among much unpublished work reported the spectrum and its partial assignment of gramicidin S, using entirely CW methodology.

The period following the introduction of the ^{13}C pulse FT spectrometer represented a phase in the evolution of ^{13}C NMR when it often sufficed to record the spectra of a few off-the-shelf compounds to produce a publication with minimal intellectual effort. However, it soon became clear that, in order to be useful, tools were needed for unambiguous spectral assignment. This problem attracted my interest during the years from about 1971–75 during my early professional career as an application scientist at Varian AG in Switzerland. First, it became obvious that the ^{13}C spectrum could not and should not be analyzed in isolation. In fact, the power of the technique was the synergism of the joint utilization of carbon and proton spectroscopy, for example, by means of ^1H – ^{13}C double resonance. One of the historic counterparts of the modern carbon–proton heterocorrelated spectrum was off-resonance CW decoupling, presumably first applied by Weigert et al.⁵ Though comparably primitive and tedious, it provided for complete cross assignment of proton and carbon resonances from a set of experiments whereby the decoupler frequency was varied incrementally. Wolfgang von Philipsborn at the University of Zürich, with whom I entertained a close working relationship highlighted in annual carbon-13 NMR workshops held throughout most of the 1970s, pointed out early on that most of the structural information resided in the proton-coupled spectrum and thus demanded an analysis of the coupling constants and their angular relationships.⁶

The ability readily to measure T_1 relaxation times by the inversion–recovery experiment, conceived by Vold et al.⁷ and Freeman and Hill,⁸ added a new dimension to ^{13}C NMR. Inspired by the mechanistic work by David Grant and his co-workers⁹ and by Lyster and Levy,¹⁰ we enthusiastically launched ourselves into applying this marvelous tool for assigning spectral resonances by making use of the structural dependence of dipolar coupling and its modulation by rotational diffusion.¹¹ A case in point is the inversion–recovery spectrum of cholestane shown in Figure 2 from which backbone methylenes can readily be distinguished from their methine counterparts and carbons belonging to the C-17 side chain, merely on the basis of their differential recovery. Many of these techniques were superseded by the emergence and rapid dissemination of two-dimensional NMR spectroscopy in the mid-1970s by the research groups of Richard R. Ernst and Ray Freeman.^{12,13}

By mid-1975 we had accumulated a considerable body of material, much of it too fragmented to warrant separate publication, but as a whole it was probably worthwhile to be shared with fellow chemists and spectroscopists. It is perhaps for this reason that Jim Feeney encouraged me to organize this material into a textbook, a task

Figure 2 Inversion–recovery ^{13}C NMR spectrum of cholestane. Backbone CH_2 carbons relax fastest (positive signals), followed by CH groups (slightly negative, dotted line), and the side-chain carbons which, by virtue of their longer T_1 values, relax most slowly. (Taken from Ref. 14 with permission)

which I enthusiastically undertook with my co-worker Toni Wirthlin.¹⁴

EXPLORING THE PERIODIC SYSTEM

Another example how technology can drive applications is multinuclear MR. The technological advance, in this instance, was the frequency synthesizer, the basis of the broadband rf transmitter. The Varian XL-100 spectrometer had a feature called the ‘Gyrocode’ decoupler, a broadband decoupler which, however, was of limited use until someone had the idea of reversing its function by adding broadband transmitter boxes and preamplifiers.

Following the ^{13}C euphoria, these developments redirected my interests toward heteronuclear NMR. Of course, many of the heteronuclei had already been studied in great detail and applied to organic, inorganic, and bioinorganic chemistry. Among these were virtually all spin- $\frac{1}{2}$ nuclei, which, however, as every NMR spectroscopist knows are a minority within the Periodic Table of the elements. While all elements have at least one magnetically active isotope, the majority of isotopes are of the spin $I > \frac{1}{2}$ type and thus quadrupolar. Many of these were discounted as being useful due to either excessively large quadrupole moments, low isotopic and chemical abundance, poor receptivity, or a combination of these adverse factors. Noteworthy exceptions were the alkali metal ions which, because of their role in biology, had been studied early; sodium by Pierre Laszlo,¹⁵ sodium and other alkali metals by Lindman and Forsén,¹⁶ and deuterium by Ian Smith and his co-workers.¹⁷ However, it was Otto Lutz in Tübingen who, with his early Bruker SXP-100, had explored the NMR properties of many of the more esoteric nuclei. His many contributions to the field are summarized in Ref. 18.

Nevertheless, to my surprise, many of the quadrupolar nuclei had hardly been observed before, and their relaxation properties were largely unknown. Among the ones I had an opportunity to study in some detail were ^6Li , ^9Be , and ^{133}Cs .¹⁸ In the course of this work, my co-workers and I felt some of the excitement the early pioneers must have experienced when first detecting a resonance signal for the purpose of measuring a nucleus’s magnetic moment. An anecdote perhaps

Figure 3 8.4 T ^{27}Al spectra showing the resonances of the mixed complexes $\text{AlS}_n(\text{H}_2\text{O})_{6-n}^{3+}$ ($\text{S} = \text{CH}_3\text{CN}$) assigned on the basis of estimated relative quadrupole coupling constants which determine the linewidth. (Taken from Ref. 20)

worth sharing with readers deals with some ^6Li experiments I conducted in 1976. Lithium-6 has $I = 1$, 7.4% natural abundance and resonates at 14.7 MHz at a field of 2.3 T; hence it should be easy to detect. To my surprise, ^6Li had, as of 1976, not yet been observed in solution (in contrast to its companion isotope, ^7Li , which was widely used in organolithium chemistry). Upon dialing the frequency of ^6Li , to my delight a signal crept across the oscilloscope. However, I was unable reproduce the finding and aborted the experiment after a while. The elusive signal reappeared in a second attempt several hours later, at which time I became certain that the observation was real. The culprit for the apparent irreproducibility, of course, was the exceedingly long T_1 value. With its very small quadrupole moment (4.6×10^{-4} b), quadrupole relaxation turned out to be almost negligible and dipolar coupling relatively weak. Nevertheless, a more detailed mechanistic analysis revealed the predominance of dipolar relaxation in aqueous solution with an observed T_1 of 3 min. In D_2O , T_1 was found to rise up to 17 min at 80°C !¹⁸

Of course these are esoterica, and it was of much more relevance to show that quadrupolar NMR could provide information on solution structure. On a trip to Moscow in 1978 I met Dr. Valerii Tarasov, a co-worker of Professor Buslaev at the Institute of General and Inorganic Chemistry. I was intrigued by a paper in which Tarasov showed that the mixed niobium halides in the ^{93}Nb spectra could be readily assigned on the basis of their symmetries which, of course, govern the quadrupole coupling constants and thus the ^{93}Nb relaxation times. Based on interatomic distances, ligand charges, and symmetry arguments, the electric field gradient tensor invariant can be computed and the relative linewidths predicted, thus permitting assignment of their resonances.¹⁹ My wife, Suzanne, and I applied this method to a number of inorganic solution systems, an example of which is given in Figure 3, showing the ^{27}Al spectra of the mixed solvates of Al^{3+} .²⁰

FROM SPECTROSCOPY TO IMAGING

My career as an NMR spectroscopist came to a temporary end upon joining General Electric Medical Systems, where I

found a world quite distant from the one I was accustomed to in my earlier career. Whereas spectroscopy, except for the very beginnings, was in its majority the accomplishment of chemists, the medical imaging arena was clearly the realm of physicists. My colleagues at General Electric were very conversant on such subjects as image reconstruction algorithms and the point spread function, concepts which were quite alien to an NMR spectroscopist but which were as much daily bread to them as chemical shifts and correlation times were to me.

We rapidly overcame the mutual knowledge gap and, to my surprise, I soon developed a liking for the intricacies of NMR imaging (or MRI—magnetic resonance imaging, the acronym favored by the American College of Radiology). This kind of cross fertilization occurred in numerous laboratories around the world and certainly greatly enhanced the rate at which MRI evolved. Unlike computed tomography (CT), which was essentially the product of corporate R&D labs, with the details of technical implementation tightly guarded secrets, the accessible knowledge base in NMR was much broader and more of it resided within academia, and was thus readily available in the open literature.

In my responsibility as the manager of magnetic resonance applications, which entailed the development of clinical applications in cooperation with academic institutions, I soon became aware of the enormous need for user education. Unlike the high-resolution NMR user (typically organic or physical chemists), radiologists had, with few exceptions, never been exposed to magnetic resonance. While the acquaintance with CT a few years earlier had been a challenge, it was nevertheless one they could master with relative ease, namely the transition from projection radiography to cross-sectional tomographic imaging. MRI was radically different and much more demanding in that they had to cope with its multiparametric nature and assimilate the property that there was no single gray scale as in X-ray imaging. Image contrast in MRI is, of course, a complete continuum, albeit one that is predictable provided the intrinsic parameters, relaxation times, and mobile water concentration ('proton density' in MRI jargon) are known. Some of my early work at GE dealt with the quantification of tissue contrast,²¹ complementing work by others^{22,23} who had recognized that understanding contrast was the key to exploiting the modality's potential. I was particularly delighted that relaxation times, whose significance in high-resolution NMR clearly trails that of the chemical shift and the spin-spin coupling constant, had a much more significant role in imaging. Like many others, we believed that a precise measurement of relaxation times could add specificity to the diagnosis. It seemed highly unlikely that two different pathologies would be identical in both relaxation times and spin density. Of course, it soon became evident that the problem was more complex and, with few exceptions—a noteworthy one being cerebral hemorrhage²⁴—pathology-induced alterations in relaxation times proved to be nonspecific. The problem is further exacerbated by the typically wide distributions of tissue relaxation times, which is not surprising when considering that pathologic tissue is often composed of a multitude of cell types.

MRI has thus remained a largely qualitative technique. Images are 'read' by a radiologist and the presence or absence of pathology assessed on the basis of local alterations in gray-scale level, in principle not fundamentally different

from the manner X-ray imaging had been practiced since its inception nearly 100 years ago. This is counter to scientific principles but, of course, clinical medicine does not claim to be an exact science, nor is it obvious to what extent image-based measurements would ultimately benefit the patient. Nevertheless, short of spectroscopic imaging which permits the measurement of metabolite concentrations, it is quite feasible quantitatively to characterize selected properties of biomaterials in vivo entirely on the basis of a bulk proton measurement. A case in point is trabecular (spongy) bone as it occurs in the major load-bearing portions of the skeleton, such as in the vertebrae. In 1989 we postulated that the anomalously short T_2^* value of the marrow protons was caused by the dipole fields induced by the bone's diamagnetism. Later we showed the intrinsic magnetic field inhomogeneity to be a function of the density, spacing, and orientation of the trabecular elements²⁵ after providing evidence that the technique may be able to detect bone loss in osteoporosis.²⁶ A more detailed account of this work is given elsewhere in this encyclopedia (See *Imaging of Trabecular Bone*).

Weitekamp, Daniel P.: Sensitivity Enhancement Through Spin Statistics

Daniel P. Weitekamp

California Institute of Technology, Pasadena, CA, USA

There are two phenomena involving nuclear spin with which every science undergraduate has at least a passing acquaintance. The first, of course, is NMR spectroscopy. The second is nuclear spin statistics, the surprising restrictions on allowed molecular states which, for example, condemn an oxygen molecule ($^{16}\text{O}-^{16}\text{O}$) to eternal rotation in its ground state. Such restrictions have few consequences for the interpretation of NMR spectra. The well-known exception is that slow interconversion between the *para* (singlet) and *ortho* (triplet) nuclear spin isomers of dihydrogen ($^1\text{H}-^1\text{H}$) may allow them to be out of equilibrium with one another over the entire course of the measurement. This disequilibrium can hold even in solution and even though other degrees of freedom, including the spin temperature of the *ortho*-hydrogen, are equilibrated. Thus, *ortho*-hydrogen and *para*-hydrogen are for many purposes distinct chemical species, the latter having only one nuclear spin state and consequently no NMR signal.

My first thoughts concerning a new connection between NMR and nuclear spin statistics¹ occurred during a visit to Caltech in the spring of 1985 that would lead to my faculty appointment there in the fall. I was having a restless night at the faculty club hotel, which I attributed to the lumpiness of the mattress, when my thoughts turned toward what was becoming my principal research interest, increasing the sensitivity of NMR by coupling nuclear spins to other degrees of freedom. The single nuclear spin state of *para*-hydrogen implies that, in a sense, it is cold. A comparable degree of spin ordering is obtainable at equilibrium only at temperatures of a few mK and magnetic fields of several tesla.

However, with no allowed transitions out of this spin state, the order of *para*-hydrogen was spectroscopically useless. It would be necessary to introduce magnetic inequivalence to release this potential signal by connecting the singlet to the triplet states. This would require chemistry, but simple bond cleavage would not suffice. A singlet state of two protons is a relationship of one spin relative to the other and this order would be dissipated if the pair were split and mixed with an ensemble of other such products. Rather, it would be necessary that the pair have a special relationship even after being distinguished by magnetic inequivalence. After moving to Caltech and opening my first inorganic text to learn that such molecular addition reactions were known, the impediment remained that I had no research assistant to try it out. In December C. R. (Russ) Bowers joined my 'group'. We prioritized a number of possible projects. The chemical relevance, simplicity, and absolute novelty of the *para*-hydrogen idea carried the day.

Russ Bowers began learning the experimental side of NMR and *para*-hydrogen production and homogeneous catalysis, while together we worked out the spin-density operator formalism of *para*-hydrogen addition and the spectroscopy of

the product molecules. We wrote up our predictions in a *Physical Review Letter* and I appended this work to a talk on another topic I was already scheduled to give at the International Society of Magnetic Resonance meeting in Rio de Janeiro in June 1986. The idea met with interest, but also with considerable skepticism that the spin order would survive the catalytic reaction. The experimental demonstration followed in July, and Russ floated around the lab in bliss, astounded that the spectrum of propionitrile, newly formed from acrylonitrile and *para*-hydrogen, looked exactly like his simulations. We published the early experiments in the *Journal of the American Chemical Society* under the title 'Para-hydrogen and Synthesis Allow Dramatically Enhanced Nuclear Alignment', but dared not to print the corresponding mnemonic (PASADENA) for fear that an acronym-adverse referee (you know who you are) would spoil our fun.

After our presentation of the first experiments at NMR meetings in 1987, it was pointed out to us that the phenomenon we predicted and demonstrated must also have been responsible for some earlier NMR signal enhancements during homogeneous hydrogenation that had been misinterpreted as the sorting of nuclear spin during the course of free-radical reactions (so-called chemically induced dynamic nuclear polarization or CIDNP), an unrelated way of inducing nonequilibrium spin populations. Although all practitioners have been won over to the Pasadena interpretation and procedure, some have so far resisted the priority (and acronymic splendor) of the PASADENA nomenclature.

The fun was soon shared with an undergraduate, Michael Pravica, who demonstrated the advantage of turning on the magnetic inequivalence adiabatically, and with a graduate student, Paul Carson, who obtained the spectrum of hydrogen chemisorption sites at a catalytic surface. Such reminiscing should not distract from the likely prospect that the chemical significance of this new connection between NMR sensitivity and nuclear spin statistics lies almost wholly in the future; very few systems have been examined. More promising still is the reverse phenomenon in which NMR of a precursor species is detected as a change in the branching ratio to spin isomers of the product hydrogen molecules, for example by optical detection of *para*-hydrogen and *ortho*-hydrogen mole fractions. This has the potential of detecting ensembles that are initially Zeeman-ordered, greatly increasing the range of accessible samples. With single-photon optical sensitivity, such an approach could enable the NMR study of individual catalytic sites.

Whiffen, David H.: Forty-Nine Years Watching NMR

David H. Whiffen

I have followed the advancement of NMR from its earliest days and have heard lectures from most of the senior practitioners and been friendly with many. I have never actually measured an NMR spectrum, which explains the title.

I was introduced to NMR when Charles Townes took me to a lecture by E. M. Purcell in Connecticut in the fall of 1946. There were excellent slides, especially of the 'eating a hole in the curve' effect, and he explained the measurement of nuclear relaxation times: my interest was great as I had measured the rotational relaxation times of molecules in nonpolar solvents.

Returning to Oxford in 1947, I found that a great friend of mine, Rex Richards, was considering what field of research he should follow as he had just become a tenured Fellow at Lincoln College and needed a change of research. He was considering NMR but he feared it would be too difficult and might be dull. Fortunately an Oxford physicist, I think Rollin, had just made the first British experiment and said it was easy. I said the relaxation times would be interesting and so Rex chose NMR; this topic occupied him all his research career.

The advances after 1947 came fast and many new phenomena not envisaged in Purcell's lecture: measurement of interhydrogen distances in solids, the *horrid* chemical shift which meant that the physicists could not agree with each other when measuring really accurate nuclear moments, the spinning of liquid sample tubes, the scalar spin-spin coupling, etc. I followed these closely and explained the science to colleagues and students in Birmingham. I remember a lecture by E. R. Andrew when he had removed the influence of internuclear coupling in solids by rapid spinning of the sample at the magic angle.

Having interesting results concerning the orientation dependence of electron resonance of radicals trapped in a single crystal, I went to a magnetic resonance Gordon Conference in the summer of 1958, as did John Pople. He explained that he had just been appointed by Gordon Sutherland to head a new Basic Physics Division of the National Physical Laboratory and was looking for a senior colleague to guide a section in magnetic resonance. As a consequence, I was appointed to this post from October 1959. John Pople and Ray Freeman were already at work. Ray Abraham, Tom Connor, Tony Hartland, and Keith McLauchlan all had several years in the NMR group. There were shorter terms for Fellows, notably David Cohen and William McFarlane. We also had many foreign visitors for extended periods of six months or more. Most of my own influence was general encouragement rather than specific advice.

My direct involvement followed a chance meeting with an old acquaintance, Dennis Evans, who told me what he had just done, namely used double resonance to show that in thallium triethyl the Tl couplings to the $>\text{CH}_2$ and the $-\text{CH}_3$ hydrogen nuclei were of opposite signs. The next day I encouraged Freeman to use double resonance to find the relative signs in a molecule with three hydrogens. The experiment was not

easy as the couplings were small but he succeeded in showing that the three couplings had the same sign;¹ we invited Evans to join us as an author but he declined as he had thought the experiment was impossible. Freeman and I published a paper showing the merit of a fixed magnetic field with one fixed and one variable frequency. The group provided several other sign determinations with such an arrangement. I suggested to Keith McLauchlan that a related philosophy would apply to double quantum transitions and we published an example; though less elegant, this required only one oscillator frequency with high power. David Cohen had a three-hydrogen case where the $J(\text{AB})$ and $J(\text{AC})$ relative signs were of interest but the usual experiment did not work because $J(\text{BC})$ was virtually zero; I explained this failure and suggested a triple resonance² experiment which was successful. There were a few other related experiments on enhancing double resonance signals, on the consequence of using very strong decoupling, on the double resonance with a spin-1 nucleus, etc., but this essentially completed my participation in NMR.

However Ray Cook and I were able to extend work in electron resonance guided by the NMR analogs and using ENDOR. The relative signs of two H couplings to the unpaired electron were determined using a double ENDOR experiment;³ this relates to the triple NMR experiment as the H-H coupling is weak. For the two H atoms in a CH_2 group in a rigid crystal, the greatest coupling is about -42 kHz when the $\text{H} \leftrightarrow \text{H}$ direction is parallel to the magnetic flux density. If the ENDOR frequencies can be measured with this accuracy, the relative signs of the ESR hyperfine couplings and the H-H coupling can be determined;⁴ this gives absolute hyperfine coupling signs as the H-H sign is certain. Other ENDOR experiments led to quadrupole coupling tensors such as that of the ^{14}N in a Type 1b diamond.

I continued a general interest and saw the early development work leading to the use of NMR in medicine, in particular, the experiments from Nottingham, where Raymond Andrew, Arthur Clough, and especially Peter Mansfield were working. The pictures provided at intervals include the NMR of a lemon, where its pips were counted and checked afterwards by cutting it open, a dead rat, a human finger, and a wrist which demonstrated how NMR was best at a bone cross section in contrast to the X-ray plates.

My interest remains and my diary contains a lecture on the medical uses to be given after this contribution is despatched. These advances and the usefulness of NMR were not remotely apparent when Felix Bloch and Edward Purcell succeeded where C. J. Gorter had, undeservedly, failed.

University, UK. Lecturer in Physical Chemistry, Birmingham University, 1949–59; FRS, 1966; National Physical Laboratory (mostly Basic Physics Division), 1959–68; Professor of Physical Chemistry, Univer-

sity of Newcastle upon Tyne, 1968–85; Retired 1985. Principal research interests: infrared spectroscopy, ESR, microwave spectroscopy, molecular force fields.

Williams, R. J. P.: The Use of NMR in Biology: Personal Reflections

R. J. P. Williams

University of Oxford, Oxford, UK

Early in the 1960s I became dissatisfied with my own studies of metal-ion interaction with molecules of biological interest. We had made many interesting observations on thermodynamic properties and UV-visible and ESR spectra but we lacked a tool for more precise structural analysis. Shortly after J. S. Anderson became a Professor of Inorganic Chemistry at Oxford he asked me about future equipment requirements. We decided to go for both NMR and ESR spectrometers. With Dr. H. A. O. Hill we chose to buy both from JEOL in 1964. We realized that our special knowledge of inorganic systems allowed us to use paramagnetic shift and relaxation probes in somewhat novel ways. We therefore applied the NMR method to structure studies of a variety of π complexes between planar metal chelates and planar organic molecules and to vitamin B₁₂. In this way we hoped to understand the interaction of metal porphyrins and chlorins with such molecules as quinones, since such interaction could have been of biological interest. Shortly after this study began (1966) I spent a year in Harvard Medical School studying metal proteins. On my return to Oxford I decided to start the NMR study of these larger molecules in parallel with model studies. The work began using a Varian 220 MHz CW spectrometer located either in a government or an industrial laboratory. The chosen protein was myoglobin since this contained the shift and relaxation probe, haem Fe (III), which could be reduced to a diamagnetic Fe (II) state giving a diamagnetic blank for comparison. In essence the experiments failed, but showed how one might succeed. The resolution was poor and with no computer backup it proved impossible to get spectra better than those demonstrated by Jardetsky's studies started somewhat earlier. All that could be seen were some histidine residues.

No real progress was made until, through a change of policy at research council funding level in Britain, we had the opportunity to bid for funding for expensive equipment opposite a research program which had to involve a large group of people. I drafted a proposal to study enzymes by NMR in parallel with crystal structure studies. Through many consultations with others, the Oxford Enzyme Group was formed and a team went out in search of a suitable company to make an FT high-field spectrometer. The team was led by R. E. Richards, K. McLauchlan, and I. D. Campbell. In fact it was found to be necessary to cobble together two companies—Bruker Spectrospin and Oxford Instruments. After a relatively short time the first FT spectrometer at high field, 270 MHz, was developed to our specification with an appropriate spectrometer suitably connected to a computer. There is no doubt that this was a major technical innovation in NMR, not mine, though stimulated by my drive to study proteins.

The spectrometer was an outstanding success in that it showed clearly that single resonances of all residues in a

protein of 15 000 Da molecular weight could be seen and studied. We chose the protein lysozyme because we had agreed to work on a protein with a known crystal structure, and when the Oxford Enzyme Group was set up it had as one leading figure Prof. D. C. Phillips, who had investigated this structure. It was an over-ambitious choice once others started work on smaller proteins! We were able to carry out spin decoupling and NOE experiments for the first time in proteins. In fact, it was clear to us all that protein structures could be studied and it became a matter of innovation in pulse sequences and in structure analysis for the objective to be reached. (See, for example, historical articles in this volume by Ernst, Freeman, and Wüthrich.) We showed, more importantly, that the dynamics of proteins could be analyzed.

The opportunity of using the high-field spectrometer also arose in the investigation of NMR in living organs. We initiated the studies of ¹H and ³¹P NMR of animal chromaffin cells of the adrenal gland (1974), the use of Gd contrast reagents for NMR scanning (1980), and of methods using shift reagents to give field gradients in the analysis of biological space (1987). These developments occurred alongside those of G. R. Radda and R. E. Richards on ³¹P NMR in muscle.

The work also led almost automatically to a chase to higher field spectrometers by manufacturers, usually with Oxford/Bruker in the lead in collaboration with the Oxford Enzyme Group technical team. Today the 750 MHz spectrometer is a direct consequence of the success of the first one built in 1971.

Of course, my group has been largely concerned with the analysis of paramagnetic molecules or molecules in which paramagnetic ions can be substituted. The finest example is the final study of cytochrome *c* using shift reagent methods. I wish to stress the value of chemical shift analysis. It uses vectors and if the analysis can be made from a single center, as in a haem protein or as in a protein such as lysozyme doped with a lanthanide, then the analysis does not require knowledge of the *g*-tensor which is left as one of the unknowns. Using a computer search, and assuming a single structure (this is not likely to be true ever, but it is a useful global view as in all NMR studies) it has to be the case that a structure can be determined.¹ There is additional value in 'diamagnetic' shift data since these readily distinguish secondary structure as shown by Clayden. Combination with relaxation scalar probes (paramagnetic or NOE) then leads to very convincing NMR structural data.² For example, the studies of cytochromes revealed which proteins changed their H-bond patterns on a change of oxidation state.³ This is fundamental knowledge since it leads to information concerning redox state changes and proton movements. The method can be greatly extended especially since mobile regions of proteins, difficult to study by NOE, are open to analysis by shift studies. It is worth noting that sections or even whole proteins of low structural content were discovered by us, e.g. chromagranin A, in a cell! Shift analysis should be very valuable in the folding problem, as shown in publications by C. M. Dobson.

The main group of people involved in this work were H. A. O. Hill, B. E. Mann, K. G. Morallee, J. A. Glasel, R. A. Dwek, A. Xavier, I. D. Campbell, C. M. Dobson, P. E. Wright, B. A. Levine, P. J. Sadler, G. R. Moore, R. G. Ratcliffe, C. F. G. C. Geraldès, F. M. Poulsen, F. Inagaki, N. J. Claydon, G. R. Williams, R. E. Klevit,

W. J. Fairbrother, Y. Gao, and H. C. Joao with the technical help of J. Boyd and N. Soffe. All of them now have considerable standing in the NMR field in their own right.

Witanowski, Michal: A Short Story about Nitrogen NMR

Michal Witanowski

Polish Academy of Sciences, Warsaw, Poland

A genuine breakthrough in chemical structure investigations was effected by the discovery of the so-called chemical shift in NMR, occurring just at the time when nitrogen NMR was involved since Proctor and Yu had in 1950 detected two ^{14}N resonance signals in ammonium nitrate. They were rather lucky since the chemical shift difference is quite significant in this case (ca. 350 ppm) and the relevant ^{14}N quadrupolar relaxations are slow. However, despite the significance of nitrogen in Nature and chemistry, further progress in the field was hampered by the inherent low sensitivity (low frequencies, about 0.1 and 0.07 for ^{15}N and ^{14}N , respectively, with respect to ^1H), a natural abundance of only 0.3% for ^{15}N (spin $\frac{1}{2}$) and its unfavorable relaxation ratio T_1/T_2 , and quadrupole relaxation effects in ^{14}N NMR (spin 1, abundance 99.7%) which yield a large range of signal widths in the spectra. It took more than 10 years after Proctor and Yu's work before nitrogen NMR started gaining some momentum.

In the early 1960s, nobody knew too much about the subject and, when we purchased our first NMR machine (a Varian HR-60) in 1962, I had to argue a lot in favor of spending an extra 10% for a nitrogen-14 rf unit and a probe head which could house 15 mm o.d. sample tubes. Fortunately, our group was deeply involved in the chemistry of organic compounds of nitrogen and the arguments were persuasive. We were quite proud of ourselves when we obtained the ^{14}N signal of neat liquid nitromethane (little wonder, in the neat liquid its concentration is 18 M and the signal width is ca. 10 Hz), and even more so when we found that a mixture of nitroalkanes showed discrete signals, spaced at about 10 ppm, which represented nitro groups attached to CH_3 , RCH_2 , R_2CH , and R_3C moieties, respectively. This was probably the first case when nitrogen chemical shifts provided a useful insight into some fine details of molecular structure, since the first larger collection of ^{14}N data by Herbison-Evans and Richards at Oxford in 1964 had suggested that the distinction of nitrogenous moieties could be achieved only in cases where large differences existed in nitrogen shifts. We encountered severe problems in obtaining ^{14}N spectra which contained overlapping signals of different widths, but we quickly discovered that the newly introduced integrator system with its audio modulation of the resonance frequency could be employed to circumvent this difficulty, by allowing simultaneous measurement of the generated sidebands together with the center-band spectrum and making use of adjustable differences in saturation levels. This gave rise to what we called the differential saturation technique in continuous-wave NMR, implemented with suitable lineshape fitting procedures and spectral accumulation.

All this improved the precision of the measurements of ^{14}N nitrogen shifts to such an extent that it led to a wealth of information about organic chemical structures. In the

meantime, during my postdoctoral stay at Caltech in J. D. Roberts's group in 1964–65, I discovered that they also had experimented with nitrogen NMR but by using ^{15}N and labeled samples. They had their problems, too; the long relaxation times of ^{15}N required, in some cases, a wait of a few minutes before starting the next field sweep in order to observe any signal at all. However, until the early 1970s and the advent of the pulsed Fourier transform NMR technique, most nitrogen NMR studies involved ^{14}N . We had a considerable share in this work, in the field of aromatic heterocycles, nitriles, nitro compounds, amines and ammonium ions, and various other nitrogenous moieties.

In 1967, I started a close collaboration with Graham A. Webb (University of Surrey), and in 1973 we edited a collective monograph on all aspects of nitrogen NMR,¹ the first such enterprise in the field. It is my impression that since then the manufacturers of NMR spectrometers have ceased considering nitrogen NMR as being relegated to the not-so-important class of 'other nuclei'. Our further studies have involved both ^{14}N and ^{15}N NMR and applications thereof in chemistry, but we have also made considerable efforts in presenting some more generalized views on nitrogen NMR and the scope of its applicability in solving chemical problems.^{2a–d,3} It is not possible to go into detail here, but the following topics are worthy of mention: the general problem of referencing nitrogen chemical shifts and evaluation of the standards, using concentric spherical sample/reference containers in order to get rid of bulk susceptibility effects; the evaluation of nitrogen chemical shift reagents and relaxation reagents; the assessment of nitrogen NMR as a means of localizing protonation sites and for following tautomeric and other chemical equilibria; the identification of isomeric structures; ^{14}N relaxation effects as an aid in nitrogen shift assignments; and nitrogen NMR as a convenient tool for investigations of molecular interactions in liquids.

Today, nitrogen NMR seems to be an important branch of NMR and, from the viewpoint of ^{15}N , its growth is associated with the high magnetic fields available and multiquantum and polarization transfer techniques combined with proton detection of nitrogen transitions, which make possible the study of proteins and nucleotides. High magnetic fields are even more important as far as ^{14}N is concerned, but in my opinion a breakthrough is likely to arrive with the advent of multichannel excitation of the spectra rather than pulse excitation with its inherent phase drifts and baseline distortions.

Woessner, Donald E.: In a Maze in NMR

Donald E. Woessner

University of Texas Southwestern Medical Center, Dallas, TX, USA

INTRODUCTION

In the autumn of 1952, I entered the University of Illinois Department of Chemistry graduate school to obtain my Ph.D. I chose to major in physical chemistry and minor in physics and mathematics. After a few months, I entered the research group of Herbert Gutowsky. The important factors in choosing Gutowsky as research advisor were the enthusiasm of his graduate students for NMR, the high regard they had for him, and the nature of NMR. Nuclear magnetic resonance was a new field and I had never heard of it before. Research in NMR appealed to me because it involved many interesting fields: chemistry, physics, electronics, and mathematics. I never regretted that decision because the field of NMR has grown continuously over the years.

After appraising my possible role in liquids high-resolution spectroscopy and solids wide-line spectroscopy, I decided to work on ^{35}Cl nuclear quadrupole resonance (NQR) of solids. To do this, I constructed a pulse nuclear resonance spectrometer¹ that was designed by John C. Buchta, a graduate student in electrical engineering. This was the first pulse machine in an academic chemistry department in the USA! Besides NQR research on ^{35}Cl in organic solids,² I used this equipment to carry out experiments such as ^1H and ^{19}F NMR relaxation in liquids,³ ^1H temperature-dependence measurements in natural rubber⁴, etc. This research started my interest in the Bloembergen, Purcell, and Pound (BPP) relaxation theory and the deviations from it due to chemical structure. Also, a chance discovery of ^1H spin-lattice relaxation via proton-chlorine nuclear spin exchange induced by manual rotation⁵ of solid *p*-dichlorobenzene in B_0 initiated my interest in chemical exchange.

THE ROLE OF NMR IN INDUSTRIAL PETROLEUM RESEARCH

John R. Zimmerman recruited me in 1958 to carry out research in the petroleum exploration and production research laboratory of Magnolia Petroleum Company in Dallas, TX (now part of Mobil Research and Development Corporation). Magnolia chemists recognized early that NMR could help solve petroleum industry problems involving the analysis of hydrocarbons and the flow and displacement of liquids in oil reservoir rocks. In 1952, at the behest of S. R. Faris, Magnolia made the first industrial purchase from Varian Associates of a wide-line spectrometer to study oil/water displacement in rocks. Purchase of a Varian Associates high-resolution NMR spectrometer for hydrocarbon analysis followed a few years later. This equipment started Mobil NMR research that continued in Dallas for 40 years, only to be totally terminated in 1992. Because pulse NMR methods should offer better

methods to measure relaxation times and quantify liquid displacement in rocks, Magnolia purchased a pulse NMR spectrometer from Varian. The pulse spectrometer was out of date when I arrived. With the electrical engineering expertise of G. L. Hoehn and then R. A. McKay, I upgraded it to state-of-the-art performance.

The objective of my early work at Mobil was to develop an understanding of the NMR signals from liquids in porous rocks. A promising new oil well logging tool based on NMR in the Earth's magnetic field was under development by an oil well service company. To make use of this tool, Mobil needed to relate the characteristics of the NMR signals to pertinent liquid properties that would allow discrimination between oil and water and the detection of porous permeable rock formations in which these liquids could flow. My early research at Mobil involved the use of NMR relaxation and diffusion experiments to understand the motions of molecules in bulk liquids and of molecules on rock surfaces. The two important surfaces are of silica and clay.

During the years that fundamental research could be carried out at Mobil in Dallas, I enjoyed close collaboration with many capable scientists who provided special insights, knowledge, and expertise. Of my coauthors, J. R. Zimmerman, provided initial encouragement to do fundamental research, E. T. Strom helped in planning much of the research on hydrocarbon liquids, and G. H. Meyer provided invaluable solutions to differential equations. B. S. Snowden provided mathematical analysis and computer programming in much of my work involving clays. In particular, Snowden emphasized the concepts of order and order/disorder transitions in affecting motions in solids, liquids, and heterogeneous systems. These collaborations contributed to much of my research which is not mentioned in this short article.

TRANSLATIONAL DIFFUSION

In a bulk liquid, the diffusion coefficient, which can be found from the attenuation of the $90^\circ\text{--}\tau\text{--}180^\circ$ spin echo at 2τ due to diffusion in a magnetic field gradient, is independent of 2τ . I had the idea that, in a porous medium, the presence of pore walls would restrict the translational diffusional displacement of the liquid molecules and thus reduce the diffusion coefficient that is obtained from the NMR method. Because only a small fraction of the molecules would encounter a pore wall when 2τ is short, the diffusion coefficient would be almost equal to the bulk liquid value. For large 2τ values, a much larger fraction of the molecules would encounter a pore wall and undergo reduced translational displacement, and the diffusion coefficient could be significantly less than that of bulk liquid. Hence, the diffusion coefficient in a rock should depend on both the 2τ value and the pore size.

To test this idea, I devised a procedure and set up the apparatus⁶ to measure the echo amplitude as a function of magnetic field gradient value at selected values of 2τ . The apparent water diffusion coefficients that I measured in a sandstone rock and in suspensions of silica spheres supported this idea. To my knowledge, my paper⁷ that described this idea and its experimental verification was the first publication of the use of NMR to study restricted diffusion. This work prompted E. O. Stejskal and his students to develop the pulse magnetic

field gradient method to study restricted diffusion (1965). Although I could not follow up my original experiments, I was pleased that they stimulated much new research.

ANISOTROPIC ROTATIONAL DIFFUSION, INTERNAL MOTION, AND RELAXATION IN LIQUIDS

My research also involved NMR relaxation to study the motions and interactions of hydrocarbon molecules in liquids. Because hydrocarbon molecules are nonspherical, I thought that they did not rotate isotropically and that a proper interpretation of the NMR relaxation in such liquids should take rotational anisotropy into account. Also, many hydrocarbon molecules, toluene and *n*-paraffins, for example, have internal motion such as reorientation of a methyl group about its fixed threefold symmetry axis. All of my magnetic dipolar calculations used pairwise interactions; the relaxing unit was a pair of nuclei that define an internuclear vector. The model in my first derivation⁸ was an internuclear vector reorienting about an axis that is fixed to a framework that is undergoing isotropic rotational diffusion. This model should also be a fair approximation for some axially symmetric liquid molecules and for molecules at surfaces. This derivation drew upon previous research. Bloembergen (1956) derived formulas for the relaxation of two magnetically coupled identical spin- $\frac{1}{2}$ nuclei undergoing hindered rotation about a fixed axis; I used his mathematical models of 120° jumps and diffusional rotation. Stejskal and Gutowsky (1958) calculated the proton T_1 of methyl groups, with magnetic dipolar coupling among the three protons, undergoing hindered reorientation within a molecule undergoing random tumbling. I used their mathematical method of treating the two independent motions. My equations show that the relaxation contributions of the types of motion are mutually dependent even if the two types of motion are completely independent. This formulation agreed more closely with the experimental data⁹ for the proton T_1 in solid *t*-butyl chloride than previous ones.

I realized from the beginning that this motional model is a special case of molecular anisotropic rotational diffusion. Accordingly, I sought the mathematical formalism for the general case and found two extremely useful papers by Perrin. The first paper¹⁰ contains a comprehensive discussion of the translational and rotational Brownian motions of a completely asymmetric rigid ellipsoid in a continuous viscous medium. In the second paper,¹¹ Perrin describes exactly what I wanted: an elegant operator method to calculate directly the rates of change of average values of orientation functions for these ellipsoids. I used this method¹² to evaluate the autocorrelation functions of the second-order spherical harmonics in the NMR relaxation interactions. My calculations also included the two models of internal motion just mentioned, applied to an axially symmetric ellipsoid in which the internal rotation axis is parallel to the symmetry axis. The final derivation¹³ allowed the internal axis to have any fixed angle with the ellipsoid symmetry axis. In both calculations, the internuclear separations were constant. I removed this constraint¹⁴ for the magnetic dipolar relaxation between protons of two different staggered neighboring methyl groups that undergo 120° jumps about the same axis. This axis is parallel to the symmetry axis of the axially symmetric ellipsoid.

I found that anisotropic motions and internal rotations in all these derivations yield multiple correlation times and have large effects on relaxation times. When a correlation time is much smaller than the others, the predictions of the BPP theory can be much in error. These theoretical results were used by us in the design and interpretation of several pioneering experiments involving anisotropic reorientation and the internal motion of organic liquids.

ANISOTROPIC REORIENTATION AND PREFERENTIAL ORIENTATION OF MOLECULES ON SURFACES

The quartz sand in oil well rock has a low specific surface area. Silica gel has a high surface area, and J. R. Zimmerman and co-workers at Mobil used it to model the rock surface. The high surface area held sufficient amounts of adsorbed water for NMR measurements even at monolayer coverages. Their pioneering NMR research (1956) showed that at room temperature this water exists in two different environmental states with different NMR relaxation times. Exchange theory analysis¹⁵ of relaxation curves showed that protons transfer at kilohertz rates between these states. My initial research extended this work to cover a range of temperatures; this would increase our understanding of the motions and structures of the water molecules interacting with the silica surface. All of this research was concurrent with my diffusion research and my theoretical and experimental work on NMR relaxation in liquids.

In my early efforts to understand the NMR relaxation times of surface water, I delved into the literature on dielectric relaxation of adsorbed water. The isotropic rotational diffusional model predicts that the NMR τ_c is one-third of the dielectric relaxation time τ_{diel} . Odajima (1959) made NMR T_2 studies of water sorbed on fibrous materials and concluded that this relationship is not obeyed for such systems. He suggested that water molecules in the sorbed state do not rotate isotropically. However, Sasaki and co-workers (1960) measured T_1 on the same systems and deduced that the τ_c that determines T_1 is one-third τ_{diel} . Because the water molecule is nonspherical in shape, in intermolecular interactions I believed that physical considerations should lead to preferential orientation and anisotropic rotation. I was hoping to find more direct experimental evidence of anisotropic reorientation than that reported by Sasaki because a distribution of correlation times for different water molecules with chemical exchange could cause the above observations.

My belief was justified and my hope was realized with the publication by Ducros¹⁶ of the proton NMR spectra of water adsorbed in the noncubic cages of zeolite single crystals. Dielectric relaxation measurements made on these crystals showed that the water is in rapid motion, similar to liquid water. Instead of the narrow singlet NMR peak of bulk liquid water, the NMR spectra consisted of a narrow doublet with a splitting that is proportional to $3 \cos^2 \alpha - 1$, where α is the angle between the optical crystal axis and B_0 . The nonzero splitting arises from molecular rotation that, although rapid, does not result in a spherically symmetric distribution of the proton–proton direction. As a result, the proton–proton magnetic dipolar coupling is not averaged out by the rapid

motion; this nonzero residual coupling represents a very long correlation time. The nonspherical symmetry is caused by the combined effects of the preferential orientation at the zeolite cage surfaces and the noncubic shape of the cages. Preferential orientation, of course, causes the rotational motions to be anisotropic with respect to the cage wall.

Besides preferential orientation and anisotropic motion, I was concerned about chemical shift effects on the measured relaxation times. Dielectric polarization measurements suggested a decrease of hydrogen bonding for monolayer water molecules (compared with bulk liquid molecules). Because the chemical shift of water is a strong function of hydrogen bonding, the T_2 of exchanging chemically shifted water molecules might be shortened by this effect.

To interpret the proton NMR signals from monolayer water on silica gel, I needed new theoretical tools. First, I derived the equations that describe the free induction signals from spin- $\frac{1}{2}$ nuclei exchanging between two different environmental states with different values of T_1 , T_2 , number of nuclei, and chemical shift.¹⁷ Next, to include the orientational effects of the surface on the relaxation, I adapted¹⁸ my first anisotropic motion model to comply with the restrictions imposed by stationary surfaces. I used this calculation, with my chemical exchange calculation,¹⁷ to interpret^{18,19} my temperature, surface coverage, and NMR frequency dependence measurements of proton T_1 and T_2 of water adsorbed on silica gel. Although the experiments did not involve enough quantifiable parameters to verify the details of the anisotropic motional model, the observations agreed qualitatively with the predicted effects of anisotropic motion. A BPP model with a single isotropic motion in each of the two environmental states disagrees with observations. However, the NMR results only inferred preferential orientation.

I found direct indications of preferential orientation in the proton relaxation measurements of benzene adsorbed on silica gel.²⁰ The transverse relaxation curves contained a Gaussian decay component that is characteristic of the free induction decay from a powder sample that has a very long τ_c value. Because the T_1 values suggested a short τ_c , this component showed an anisotropic orientation distribution (preferential orientation) of benzene molecules with respect to the silica gel surface.

PREFERENTIAL ORIENTATION, DIFFUSION, AND ORDER IN AQUEOUS HETEROGENEOUS SYSTEMS

The following observations initiated my theoretical and experimental research into the use of quadrupolar and magnetic dipolar splitting from preferential orientation to probe order and structure in aqueous heterogeneous systems.

Because natural smectite clays, such as montmorillonites, contain significant quantities of paramagnetic iron centers, my early research on clay/water interaction used deuterium NMR measurements on D_2O /montmorillonite gels. Such smectites consist of parallel 10 Å thick aluminosilicate sheets stacked like leaves in a book. When the exchangeable cations are Li^+ or Na^+ , montmorillonite will absorb large quantities of water and retain a pseudocrystalline structure. To assess the effects of the paramagnetic centers on hydrogen T_1 and T_2 , I made a D_2O /clay gel with about 20 wt% clay. Before making the

deuteron measurement, I tuned the probe and set the 90° – 180° pulse sequence with a vial of D_2O . Then I inserted the vial containing the D_2O /clay gel to optimize the probe tuning and pulse widths. I observed a beautiful FID after the 90° pulse; however, the expected spin echo at time 2τ was missing. Thinking that the gel had loaded-down the probe, I retuned the probe and reset the 90° pulse with the gel in the probe. The previous tuning and 90° pulse settings proved to be correct; therefore, the initial 180° pulse setting should be correct! I shortened the second pulse (why, I do not know); a spin echo appeared at time 2τ and its amplitude was a maximum at the setting for the initial 90° pulse. This behavior was completely unexpected and I had no idea of how to explain it.

Serendipitously, a few days later I received a copy of the paper by Powles and Mansfield²¹ that described and explained the proton solid echo in gypsum. Their experiments were the same as mine, except that I used the deuterium NMR resonance of the D_2O /clay gel. Because their observations were caused by the proton magnetic dipolar splitting, I thought that my observations might be caused by residual deuterium quadrupolar splitting from preferential orientation of the D_2O molecule at the clay surface. I derived the 90° – τ – 180° and 90° – τ – 90° pulse NMR signals for spin-1 nuclei with static quadrupole interaction and found the same behavior as reported by Powles and Mansfield. The effect of the 180° pulse refocuses the loss of signal amplitude due to B_0 inhomogeneity so that the amplitude at time 2τ is independent of this inhomogeneity. In this calculation, the second 90° pulse refocuses the loss of signal amplitude due to the spread in quadrupole interaction because of the anisotropy for crystallites in a powder sample.

Preferential orientation of liquid molecules at the surfaces of minerals and biomacromolecules provides a unique NMR tool to investigate the ordering of such surfaces in aqueous heterogeneous systems. Of course, preferential orientation means that the relaxation interactions and spectral line splitting depend on the orientation of the surface with respect to B_0 . Key verifications can be made by making 'oriented' samples and observing whether the relaxation effects obey the $3 \cos^2 \theta - 1$ dependence on this orientation.

The idea that evolved is based on interfacial molecules that are in rapid motion and are preferentially oriented. This causes NMR *spectral splitting* of these molecules that depends on the orientation of the interface in B_0 . Rapid *chemical exchange via translational diffusion* between these molecules and the nearby bulk liquid causes all of the molecules to occupy the interfacial location in a time that is short compared with the reciprocal of the interfacial splitting. As a result, all of the molecules exhibit an NMR spectral splitting. This splitting is reduced from that of the interfacial molecules. The reduction factor is the fraction of the molecules that are in the interfacial locations at any instant. Snowden and I verified²² this by simulation and by NMR experiments on oriented montmorillonite samples that contained interfaces that were essentially parallel. The water in such oriented samples has T_1 , T_2 , and spectral splitting values that depend on the interface orientation in B_0 .

Now we introduce ordering. Consider a sample comprising many crystallites arranged in totally random orientations in B_0 . Molecules undergo *translational diffusion* within and between the crystallites. When the crystallite size is large compared with the diffusion distance in the time in the NMR experiment, the net result is a static 'powder' pattern that is the superposition of the NMR signals. If the diffusion

distance is comparable to or larger than the crystallite size, the former static powder pattern is modified. The shape of the NMR response in various pulse sequences depends on the different splittings and relaxation times that the molecules experience over their diffusional paths. The average lifetime for a molecule to diffuse from a crystallite of a given orientation to one of approximately 1 rad different orientation is the correlation time τ_{cry} . We used two parameters, S and τ_{cry} , to simulate the effects of preferential orientation in several models of migration. These models represent different types of 'order' in the sample.

Our first simulation²³ was an isotropic 'rotational diffusion' model in which the change in orientation θ between successively occupied crystallites is small. We calculated the signal after a 90° pulse as a function of time t . We also calculated the amplitude of the solid echo at time $t = 2\tau$ as a function of τ . Both curves depend on both the splitting constant S and τ_{cry} . Except in the case of very small τ_{cry} values, these curves have different dependencies on t . Therefore, these results enabled us to evaluate both S and τ_{cry} from an analysis of experimental curves. Using these values, we could simulate the deuteron NMR signal amplitudes in the time from $t = 0$ to $t = 5\tau$ in a sequence of three 90° pulses applied at times 0, τ , and 3τ . This simulation reproduced the shape and shift of the first echo that I observed (January 13, 1969). The peak of the first deuteron solid echo in clay gels occurs *before* the expected time 2τ but that of the second echo occurs *at* the expected time 4τ . This shift of the spin echo peak *does not* occur in aqueous paramagnetic ion solutions in an inhomogeneous B_0 , for example.

We had the idea that small changes in consecutive θ values might not always be realistic. To test this, we undertook the analogous calculation²⁴ of the pulse NMR signals resulting from random reorientation of the nuclear interaction vector among the four orientations described by the four vectors joining the center and each of the four vertices of a fixed regular tetrahedron. The result was obtained by averaging over all tetrahedron orientations. Both models give approximately the same S values. The main difference lies in the motion that is lumped into τ_{cry} . The translational diffusion path is different for the two models and τ_{cry} is sensitive to this difference. Experimentally, the shape of the signal following two 90° pulses is more sensitive to diffusional path than that following a single 90° pulse. For many clay-water systems, the two-pulse signal more closely approximates the signals generated with the tetrahedral model.

The work just described shows the power of NMR to study dynamics and ordering of water molecules in interfacial systems and of the ordering of the interfaces themselves. This is illustrated by our work²⁵ on D₂O solutions of the biopolymer Kelzan. We detected and measured partially ordered domains of macromolecules in these solutions. The rate for a molecule to diffuse from a domain is proportional to the diffusion coefficient. We measured the diffusion coefficients at two different temperatures and evaluated the τ_{cry} values with the two models. The tetrahedral model is superior in describing this system. Also, deuteron NMR measurements show that various physical treatments greatly affect the size of the domains. Stirring increases the distance of long-range ordering because of the flow lines and heating decreases it.

Years later, other researchers²⁶ used an analogous model to explain the transverse NMR relaxation of ²³Na in solutions of

linear polyelectrolytes. Because macromolecular order occurs in biological tissue, this model should be applicable to the interpretation of NMR relaxation in medical applications of NMR. Actually, anisotropy of the proton T_2 in skeletal muscle and that of the ²³Na in hydrated Na⁺ ions in tendon is observed. The diffusional paths of water and hydrated ions in tissue should be like wanderings in a maze; the arrival of clinical magnetic resonance imaging emphasizes the importance of understanding it.

Biographical Sketch

Donald E. Woessner. b 1930. A.B., 1952, Ph.D. (supervisor Herbert Gutowsky), 1957, Chemistry, University of Illinois, USA. Postdoctoral work at University of Illinois (with Herbert Gutowsky). Successively senior research chemist, research associate, senior research associate, Mobil Research and Development Corporation, Dallas, Texas, USA. Currently Adjunct Assistant Professor of Radiology, The University of Texas Southwestern Medical Center at Dallas, 1992–present. Approx. 70 publications. Research specialties: NMR relaxation and molecular motions in liquids; relationships of NMR relaxation of hydrogen and ionic nuclei to motions, structure and order in aqueous heterogeneous systems and biological tissue.

Wrackmeyer, Bernd: A Personal Retrospect of Multinuclear Magnetic Resonance in Liquids

Bernd Wrackmeyer

Universität Bayreuth, Bayreuth, Germany

A strong relationship between chemistry and NMR had been firmly established since the late 1960s. However, the NMR equipment in most laboratories was not really advanced, in spite of the first cryomagnetic systems on the market and the beginning of pulse Fourier transform (PFT) NMR (R. R. Ernst and W. A. Anderson, 1966). At that time it was widely accepted that all major applications of NMR could be identified with organic chemistry. Of course, research in inorganic and organometallic chemistry already flourished using ^1H and ^{19}F NMR, but measurements of other nuclei, even of rather NMR-sensitive nuclei such as ^{11}B or ^{31}P , were far from common. There were no such things as multinuclear probeheads or handy frequency synthesizers with broadband amplifiers. Other techniques for multinuclear MR like INDOR or, generally, heteronuclear double resonance experiments, e.g. $^1\text{H}\{\text{X}\}$ or $^{19}\text{F}\{\text{X}\}$, were used only in a few places.

When I started research work in inorganic chemistry at the University of Munich in 1970, I was very lucky to work in the group of Professor H. Nöth, who began very early on to apply NMR, especially ^{11}B NMR, to inorganic syntheses. My task was to continue with ^{11}B NMR, but also to work with ^{14}N NMR (see Figure 1) and in general to make use of the ‘multinuclear’ Varian HA-100 spectrometer, equipped for CW (continuous wave) measurements of the ^1H , ^{11}B , ^{14}N , ^{19}F , and ^{31}P nuclei.

The appetite for multinuclear MR was growing. Lacking other equipment, we adjusted the magnetic field strength in order to employ the ^{14}N NMR probehead and the transmitter (7.2 MHz) for measuring other NMR-sensitive nuclei such as ^6Li , ^9Be , ^{10}B , ^{23}Na , ^{27}Al , ^{35}Cl (see Figure 2), ^{51}V , or ^{59}Co , to name just a few examples.

In the meantime, PFT NMR began to show its enormous power, the idea of two-dimensional (2D) NMR had been introduced (J. Jeener, 1971), and impressive instrumental developments became apparent, naturally with an emphasis on ^1H and particularly on ^{13}C NMR.

For multinuclear MR of less sensitive nuclei (e.g. ^{15}N , ^{29}Si , ^{77}Se , ^{119}Sn , ^{199}Hg , ^{207}Pb , etc.), heteronuclear double or triple resonance experiments, $^1\text{H}\{\text{X}\}$, $^{19}\text{F}\{\text{X}\}$, or $^1\text{H}\{\text{X}, \text{Y}\}$, remained attractive. Again I was lucky; I stayed for one year (1974–75) with the group of Professor W. McFarlane in London and became better acquainted with these techniques and their potential. These were still CW measurements, but at that time it was already clear (even without foreseeing the ever-increasing impact of electronic data handling) that developments in PFT NMR would eventually lead to comparable experiments with much greater scope and sensitivity.

The end of the 1970s marked the first turning point for multinuclear PFT MR. Probeheads or inserts became

Figure 1 7.23 MHz (2.35 T) ^{14}N NMR spectrum [single scan, CW (continuous wave), Varian HA-100] of a saturated solution of N, N', N'' -triethyltriisocyanatoborazine in CH_2Cl_2 . The two different ^{14}N resonances show severe overlap. The calibration was achieved using the ‘sideband’ method (2016 Hz modulation) with a tube containing neat nitromethane as an external reference (tube exchange during continuous field sweep)

Figure 2 7.23 MHz (1.69 T) ^{35}Cl NMR spectrum [single scan, CW (continuous wave)] of chlorodimethylsilane [$\text{Me}_2\text{Si}(\text{Cl})\text{H}$], 50% solution in pentane. The line is so broad that the centerband and sidebands (2016 Hz; for calibration) are not well separated. The ^{35}Cl NMR signal of HClO_4 (60% solution in H_2O) serves as an external reference via sample exchange

commercially available which were tunable over a wide range of frequencies [e.g. including the most common nuclei with frequencies between $\Xi(^{41}\text{K}) = 2.565 \text{ MHz}$ and $\Xi(^{31}\text{P}) = 40.481 \text{ MHz}$ (for $\Xi(^1\text{H}) = 100\,000 \text{ MHz}$)] without serious loss of sensitivity as compared with selective probeheads. Together with the steadily advancing computer control of most spectrometer functions (the age of pulse sequences had begun), truly multinuclear MR started to become a powerful tool in many different fields of research. In contrast with conventional ^1H or ^{13}C NMR measurements, nondeuterated

Figure 3 74.6 MHz (4.7 T) ^{119}Sn NMR spectrum (PFT, mode, 5000 transients, ^1H broadband decoupled, Bruker WP-200) of an equilibrated mixture resulting from the exchange reaction between $[\text{Me}_2\text{SnSe}]_3$ and $[\text{Ph}_2\text{SnS}]_3$ in CHCl_3 . The mixture contains 20 different six-membered rings which should give rise to 40 separate ^{119}Sn NMR signals of which 39 are resolved. The signals with small intensities are ^{119}Sn , ^{117}Sn , and ^{77}Se satellites corresponding to the coupling constants $^2J(^{119}\text{Sn}, ^{119}\text{Sn})$, $^2J(^{119}\text{Sn}, ^{117}\text{Sn})$, and $^1J(^{119}\text{Sn}, ^{77}\text{Se})$, respectively, which can be used for further assignments

solvents could be used. Hence, reactions could be monitored under realistic conditions, if necessary at variable temperature, observing the NMR signals of relevant nuclei, one after the other, without changing probeheads. In this way it was possible to detect reactive intermediates, to gain information on reaction mechanisms, and to influence the final product distribution by controlling the progress of reactions under carefully designed conditions. The great potential of multinuclear MR as a nondestructive method for the analysis of complex mixtures is shown for ^{119}Sn NMR as an instructive example (see Figure 3).

The theory of NMR parameters was already fairly advanced at the beginning of the 1950s (N. F. Ramsey, 1950–52). However, experimental data for testing theoretical models were often only provided much later by multinuclear MR. A good example is the question as to whether a nonrelativistic treatment is sufficient for explaining NMR data. NMR measurements of heavy nuclei and studies of the influence exerted by heavy nuclei on the NMR parameters of other nuclei showed that relativistic effects have to be taken into account. Extreme bonding situations should be reflected by NMR parameters. In this context, the high nuclear magnetic shielding of the alkali metal anions (Na^- , K^- , Rb^- , Cs^-) with respect to the cations is worthy of mention. In the context of the multifarious chemistry of the transition metals, we can learn from metal NMR many new aspects of the relationship between NMR parameters and structure on a molecular level.

The interplay between chemistry and the availability of suitable analytical tools is well recognized. Thus, from 1975 onwards, my interest in inorganic and organometallic chemistry has focused more strongly on elements which are attractive from the multinuclear MR point of view. Although there are at least one, or often more, magnetically active nuclei for almost any element, the individual magnetic properties are very different. Thus, most spin- $\frac{1}{2}$ nuclei in particular, in addition to ^1H and ^{13}C , and many of the numerous quadrupolar nuclei (spin $I > \frac{1}{2}$), are good candidates for multinuclear MR in solution. Here it is important to note that direct structural information obtained by X-ray analysis of crystalline material can now be related to NMR data in solution if solid state NMR data are known. Developments in solid state NMR, starting in the 1970s, have given access to these data. The greater sensitivity of the nuclear magnetic shielding of the heavier nuclei (as compared with ^{13}C) is particularly helpful for demonstrating even small changes in the molecular structure.

The advent of PFT NMR also helped to overcome some major problems in the measurement of both sensitive and many insensitive nuclei. However, the detection of the NMR signals of a number of prominent and important rare spin- $\frac{1}{2}$ nuclei such as ^{15}N [the abundant ^{14}N (99.63%) has a spin $I = 1$] or ^{29}Si remained difficult because of their small magnetic moment and/or unfavorable relaxation properties (e.g. negative NOE of unknown quantity and/or long longitudinal relaxation times

Figure 4 30.4 MHz ^{15}N NMR spectrum of a heterocyclic organolead compound using the refocused INEPT pulse sequence [based on long-range coupling constants $^3J(^{15}\text{N}, \text{Si}, \text{C}, ^1\text{H}) \approx 1.3 \text{ Hz}$ with ^1H decoupling]. Satellite signals arising from ^{207}Pb – ^{15}N and ^{29}Si – ^{13}C spin–spin coupling are marked by asterisks and arrows, respectively

T_1). Polarization transfer from ^1H to insensitive X nuclei, based on scalar X– ^1H spin–spin coupling [$J(\text{X}^1\text{H})$] using hard, nonselective pulses (G. A. Morris and R. Freeman, 1979) provided a very useful answer to these problems. Thus, pulse sequences known as INEPT or DEPT (based on a slightly different approach), or modifications of these experiments, allowed sensitivity problems to be circumvented. NMR signals of X are enhanced by a factor of $\gamma(^1\text{H})/\gamma(\text{X})$ (for $\text{X} = ^{15}\text{N}$, this factor is 9.86) and the recycle time of the experiment no longer depends on long $T_1(\text{X})$ values but on comparatively short $T_1(^1\text{H})$ values. Since the approximate magnitude of many coupling constants $^1J(\text{X}, ^1\text{H})$ is known, the widespread application of this method to multinuclear MR became a logical consequence. It turned out that even very small long-range coupling constants $^nJ(\text{X}, ^1\text{H})$ (as low as 0.5 Hz) can form the basis for polarization transfer (see Figure 4), although the efficiency is somewhat reduced. Clearly, once again ^{13}C NMR was the center of interest, since 2D $^{13}\text{C}/^1\text{H}$ heteronuclear shift correlations (HETCOR) based on INEPT or DEPT, taking advantage of one-bond or of long-range coupling constants $J(^{13}\text{C}, ^1\text{H})$, proved extremely useful in structural elucidation. The value of 2D HETCOR experiments of the general type $\text{X}/^1\text{H}$ has been realized not just for the mutual assignment of ^1H and X resonance signals, but also for the determination of relative signs of coupling constants (see Figure 5). A knowledge of the coupling sign is essential for the discussion of this parameter.

An inspection of the literature over the last two decades leaves no doubt about the role of polarization transfer techniques in ^{15}N NMR (at the natural abundance of ^{15}N , i.e. 0.37%) which has emerged from a shadowy existence into an active research area. The same is true for ^{29}Si NMR (see Figure 6) which has become an indispensable tool in organosilicon chemistry. Furthermore, in organometallic chemistry one

Figure 5 Two-dimensional (2D) $^{13}\text{C}/^1\text{H}$ heteronuclear shift correlation (HETCOR) of an organolead compound based on a long-range coupling constant $^3J(^{13}\text{C}, \text{Pb}, \text{C}, ^1\text{H})$ (full line in the formula). The ^{207}Pb nucleus (*) is the passive spin and the signs of the coupling constants $^1J(^{207}\text{Pb}, ^{13}\text{C})$ and $^2J(^{207}\text{Pb}, ^1\text{H})$ (dashed lines) are compared. The latter is known to have a negative sign. The positive tilt of the cross peaks (dashed line) proves that $^1J(^{207}\text{Pb}, ^{13}\text{C})$ and $^2J(^{207}\text{Pb}, ^1\text{H})$ have the same sign. Hence $^1J(^{207}\text{Pb}, ^{13}\text{C})$ must be negative (the first example of a tetraorganolead derivative)

Figure 6 59.6 MHz ^{29}Si NMR spectrum of a mixture (in toluene at -40°C) resulting from the exchange reaction between the dimeric stannylene **1**(Sn/Sn) and the dimeric plumbylene **2**(Pb/Pb) using the refocused INEPT pulse sequence, based on $^2J(^{29}\text{Si}, \text{C}, ^1\text{H})$ with ^1H decoupling. Consistent with ^{119}Sn and ^{207}Pb NMR spectra, which show four intense resonance signals each, dimers are mainly formed from two four-membered or two five-membered rings (signals marked by an asterisk may arise from a combination of four- and five-membered rings)

Figure 7 75.5 MHz ^{13}C NMR of a cyclopentadienyl rhenium complex. The detection of the ^{13}C NMR signal of the substituted carbon atom C-1 may be difficult. (a) Normal ^{13}C NMR spectrum, ^1H decoupled: the signal of C-1 is just visible; (b) if the spectrum is recorded using the refocused INEPT pulse sequence, based on coupling constants $^{2,3}J(^{13}\text{C}, ^1\text{H}) \approx 7.5\text{ Hz}$ with ^1H decoupling, the signal of C-1 is observed at the same time with a much better signal-to-noise ratio which even allows the detection of the ^{77}Se satellite signals (*) due to $^1J(^{77}\text{Se}, ^{13}\text{C})$

frequently encounters ‘difficult’ ^{13}C nuclei. Again polarization transfer can provide the magic cure for such problems (see Figure 7).

Since NMR is an inherently insensitive method, it follows that in the absence of scalar X– ^1H coupling polarization transfer cannot work, and other techniques for enhancement, similar to cross polarization in solids, are not straightforward in solution. Thus, even if one nucleus is 100% abundant, such as ^{31}P , it may be difficult to record a ^{15}N NMR spectrum of a phosphorus–nitrogen compound in order to measure the coupling constant $^1J(^{31}\text{P}, ^{15}\text{N})$. In principle, it should instead be possible to record the ^{31}P NMR spectrum with a view to identifying the ^{15}N satellite signals, or in general to record the X NMR spectrum as a means of measuring $^1J(\text{X}, ^{15}\text{N})$ if the NMR sensitivity of X is higher than that of ^{15}N , especially if polarization transfer from ^1H to the X nuclei is feasible. However, the intensities of these ^{15}N satellites are very low (0.18%), and hence partial suppression of the parent line due to the X^{14}N isotopomer is necessary. This is readily achieved by *Hahn-echo extended* (HEED) pulse sequences (Ě. Kupče and E. Lukevics, 1988; B. Wrackmeyer and Ě. Kupče, 1991)

Figure 8 121.5 MHz ^{31}P NMR; application of the HEED-INEPT experiment to 2-*t*-butyl-1,3-dimethyl-1,3,2-diazaphospholidine. Isotope effects are indicated on the top of the diagram. (a) The delay in the Hahn-echo pulse train is selected in order partly to suppress the parent ^{31}P NMR signal of the ^{14}N – ^{31}P – ^{14}N isotopomer and to observe the still broadened doublet of the ^{15}N – ^{31}P – ^{14}N isotopomer. (b) A longer delay in the Hahn-echo pulse train leads to complete suppression of the ^{31}P NMR signals of ^{14}N – ^{31}P – ^{14}N and ^{15}N – ^{31}P – ^{14}N isotopomers, leaving the sharp triplet of the ^{15}N – ^{31}P – ^{15}N isotopomer. The combined intensity of the triplet is only 1.4×10^{-5} as compared with the parent line (=1)!

taking advantage of the faster decay of the transverse X magnetization of the X^{14}N isotopomer. In 1D spectra, coupling constants $^1J(\text{X}, ^{15}\text{N})$ can be measured together with isotope-induced shifts, $^1\Delta^{15/14}\text{N}(\text{X})$, at natural abundance (Figure 8). In the past the latter parameter has received little attention in multinuclear MR since its determination is very difficult without ^{15}N labeling. Other important information can be gained in 2D X/ ^1H HEED–HETCOR experiments which is again hardly accessible by conventional techniques, even if ^{15}N labelled compounds are available. In addition to the information on the relative signs of coupling constants $J(\text{X}, ^{15}\text{N})$ and $J(^{15}\text{N}, ^1\text{H})$, the value of long-range coupling constants $J(^{15}\text{N}, ^1\text{H})$ can be measured accurately (see Figure 9), which is strategically important for obtaining ^{15}N NMR by polarization transfer techniques. All major developments in NMR focus on improve-

Figure 9 121.5 MHz Two-dimensional (2D) $^{31}\text{P}/^1\text{H}$ Hahn-echo extended heteronuclear shift correlation (HEED-HETCOR) of 2,5-dimethyl-1,2,3-diazaphosphole, based on $^2J(^{31}\text{P},^1\text{H})$ (connected by the full line). The ^{31}P projection shows the doublet of the $^{31}\text{P}-^{15}\text{N}$ isotopomer. The magnetization of the parent signal due to the $^{31}\text{P}-^{14}\text{N}$ isotopomer has decayed completely during the Hahn-echo pulse train (2×40 ms). The doublet in the ^1H projection represents the coupling constant $^3J(^{15}\text{N},\text{P},\text{C},^1\text{H}) \approx 6$ Hz (this value can be used for polarization transfer from ^1H to ^{15}N in order to obtain ^{15}N NMR spectra). With ^{15}N as the passive spin (connected with the active spins ^{31}P and ^1H by dashed lines), the negative tilt of the cross peaks demonstrates that the signs of $^3J(^{15}\text{N},\text{P},\text{C},^1\text{H})$ and $^1J(^{31}\text{P},^{15}\text{N})$ are opposite (from other experiments it is known that $^1J(^{31}\text{P},^{15}\text{N}) > 0$; therefore it follows that $^3J(^{15}\text{N},\text{P},\text{C},^1\text{H}) < 0$)

ments in sensitivity. Interestingly, one of the first 2D heteronuclear shift correlations (A. A. Maudsley, L. Müller, and R. R. Ernst, 1977) was of the type $^1\text{H}/^{13}\text{C}$, using ^1H detection (later called inverse or reverse detection) instead of ^{13}C . Clearly, the nucleus with higher NMR sensitivity should be given priority in such experiments. However, with most commercial spectrometers it was only possible to perform 2D $\text{X}/^1\text{H}$ HETCOR experiments until the end of the 1980s, mainly because of the convenience of simpler hardware. For multinuclear MR of low γ spin- $\frac{1}{2}$ nuclei inverse 2D $^1\text{H}/\text{X}$ experiments are very attractive because of the greater sensitivity as compared with the 2D $\text{X}/^1\text{H}$ version. There is also a wealth of information to be gained, as can be seen in Figure 10 in the inverse 2D $^1\text{H}/^{15}\text{N}$ HETCOR spectrum in the case of a phosphorus–nitrogen compound. It should be noted that there are serious problems in detecting the NMR signals of insensitive X nuclei if they are broadened, e.g. by partially relaxed scalar coupling to a neighboring quadrupolar nucleus. This broadening effect is normally negligible for ^1H nuclei which have a scalar coupling with X, and 2D $^1\text{H}/\text{X}$ HETCOR experiments are then very efficient (B. Wrackmeyer and Ě. Kupče, 1992; see Figure 11).

Such inverse 2D $^1\text{H}/\text{X}$ experiments can also be modified for the measurement of coupling constants between rare spin- $\frac{1}{2}$ nuclei (e.g. ^{15}N , ^{13}C ; ^{15}N , ^{29}Si ; or ^{13}C , ^{29}Si), using ^1H sensitivity. For this purpose a preselection of one spin pair (e.g. ^{13}C , ^1H) is undertaken in the first part of the experiment in order to eliminate magnetization from the $^1\text{H}(^{12}\text{C})$ isotopomer. In the second part, the X resonance is detected inversely by 2D

Figure 10 500.13 MHz two-dimensional (2D) inverse $^1\text{H}/^{15}\text{N}$ heteronuclear shift correlation of an aminofluorophosphane. The ^{15}N projection (not shown) of the correlation map gives information on the chemical shift $\delta^{15}\text{N}$ and coupling constants $^1J(^{31}\text{P},^{15}\text{N})$ and $^2J(^{19}\text{F},^{15}\text{N})$. The ^1H projection shows the spectrum of the ^{15}N isotopomer in the NH region with the splitting pattern due to spin–spin coupling $^{15}\text{N}-^1\text{H}$, $^{31}\text{P}-^1\text{H}$, and $^{19}\text{F}-^1\text{H}$. The tilt of the cross peaks in the correlation map can be used to compare the signs of coupling constants (see also Figure 5) because either ^{19}F or ^{31}P serve as the so-called passive spin in relation to the active spins ^1H and ^{15}N

$^1\text{H}/\text{X}$ correlation. This experiment may be called a pseudo-triple-resonance experiment (Ě. Kupče and B. Wrackmeyer, 1992), e.g. $^1\text{H}\{(^{13}\text{C})\text{X}\}$, in which the ^{13}C nucleus acts as a passive spin (see Figure 12). Modern NMR spectrometers are often equipped with several independent frequency channels. Together with suitable probe heads, triple resonance experiments, $^1\text{H}\{\text{X},\text{Y}\}$ or $\text{X}\{^1\text{H},\text{Y}\}$ etc., are feasible, thus further enriching the existing wealth of 2D and 3D NMR experiments.

A major problem in multipulse NMR experiments concerns phase cycling in order to eliminate small errors in pulse length and phases. Thus, more transients are often necessary than are strictly required in relation to the NMR sensitivity of a particular nucleus. This is rather annoying in 2D $^1\text{H}/\text{X}$ measurements where, in many cases, a single transient for each X frequency would be sufficient. Since the resonance frequencies

Figure 11 500.13 MHz two-dimensional (2D) inverse $^1\text{H}/^{119}\text{Sn}$ heteronuclear shift correlation of a mixture of boron–tin compounds [exchange reaction between $(\text{Me}_3\text{Sn})_2\text{B}-\text{N}^i\text{Pr}_2$ and $\text{B}(\text{OMe})_3$]. The ^1H projection shows the spectrum in the region of the Me_3Sn groups, with the selection of the respective ^{119}Sn isotopomers marked as doublets (a), (b), and (c). The ^{119}Sn projections demonstrate that it would be difficult to record a ^{119}Sn NMR spectrum of a dilute reaction solution within a reasonable time because of the broad ^{119}Sn NMR signals arising from the large coupling constant $^1J(^{119}\text{Sn}, ^{11}\text{B}) \approx 1000$ Hz. Furthermore, the detection of the unstable compound $\text{Me}_3\text{Sn}-\text{B}(\text{OMe})_2$ (b) would be extremely difficult in view of the overlap with the intense ^{119}Sn resonances of (a) and (c). In the correlation map, the cross peaks of species (b) are readily resolved

of X nuclei may cover a large range (in general much larger than for ^1H), many experiments are required in the inverse 2D experiment in order to maintain a reasonable digital resolution in the F_1 domain (X). Together with phase cycling, this uses a great deal of spectrometer time. Pulsed field gradients, in combination with rf pulses (already suggested in 1978 by A. A. Maudsley, A. Wokaun, and R. R. Ernst) circumvent the problem of phase cycling, and as a result the dynamic range problem in multiple quantum experiments is solved, and the t_1 noise in 2D spectra is considerably reduced. This latest development in multidimensional NMR in solution could have a significant influence on multinuclear MR.

The potential of multinuclear MR is now being increasingly exploited by the scientific community. The need for a multinuclear approach is reflected by the commercial availability of very flexible NMR instrumentation. There are still many problems to solve in order to handle better the NMR spectroscopy of insensitive, but important spin- $\frac{1}{2}$ nuclei (e.g. ^{57}Fe , ^{187}Os), or the problem of extremely broad lines in the absence of symmetrical surroundings with quadrupolar nuclei, (e.g. ^{35}Cl , ^{75}As , ^{139}La , ^{181}Ta , etc.), to name just two areas. This means

Figure 12 500.13 MHz two-dimensional inverse (^1H detected) pseudo-triple-resonance experiment of the type $^1\text{H}\{(^{13}\text{C})^{29}\text{Si}\}$ for tetramethoxysilane $\text{Si}(\text{OMe})_4$. This relates the spins ^1H , ^{13}C , and ^{29}Si in order to determine the small coupling constant $^2J(^{29}\text{Si}, \text{O}, ^{13}\text{C})$ and its sign. In the ^1H projection, the small residual signal of the parent line is still detected (*). The other signals correspond to the $^1\text{H}-^{13}\text{C}-^{29}\text{Si}$ isotopomer with the spin–spin coupling $^1J(^{13}\text{C}, ^1\text{H})$ and $^3J(^{29}\text{Si}, \text{O}, ^1\text{H})$. The cross peaks are separated by $^2J(^{29}\text{Si}, \text{O}, ^{13}\text{C}) = 1.2$ Hz, and the negative tilt demonstrates that the reduced coupling constants $^1K(^{13}\text{C}, ^1\text{H})$ (known to be >0) and $^2K(^{29}\text{Si}, \text{O}, ^{13}\text{C})$ [>0 ; since $\gamma^{29}\text{Si} < 0$, it follows that $^2J(^{29}\text{Si}, \text{O}, ^{13}\text{C}) > 0$] are of opposite sign. It should be pointed out that such small couplings cannot be measured from ^{13}C NMR spectra

that the fruitful mutual interaction between the development of NMR methods and chemistry will continue to produce exciting results.

Biographical Sketch

Bernd Wrackmeyer. *b* 1947. Diploma, Munich, 1971, Dr. rer.nat, Munich, 1973, Habilitation, Munich, 1979. Introduced to NMR by H. Nöth and W. McFarlane. Institute of Inorganic Chemistry, University of Munich, 1979–1986. Laboratory of Inorganic Chemistry, University of Bayreuth, 1986–present. Approx. 320 publications, and, with H. Nöth the book ‘Nuclear Magnetic Resonance Spectroscopy of Boron Compounds’. Research interests include developments of NMR techniques in solution, application of multinuclear MR to problems in inorganic and organometallic chemistry.

Wüthrich, Kurt: NMR Structures of Biological Macromolecules

Kurt Wüthrich

Eidgenössische Technische Hochschule, Zürich, Switzerland

My first job in the field of NMR with biological macromolecules started on October 1, 1967, when I joined the Biophysics Department at Bell Telephone Laboratories in Murray Hill, NJ. The department was headed by Dr. Robert G. Shulman, whose NMR credentials at the time included solid state work on metal compounds, which had attracted my interest because of the implications in the area of crystal field theory, and studies of nucleic acids and proteins in solution using relaxation enhancement techniques. My initial assignment was in line both with my previous work (see below) and with a project pursued at the time by the Bell group: substitution of the Zn^{2+} ion in carboxypeptidase A (CPA) by VO^{2+} to enable ^{17}O relaxation enhancement studies of the active site hydration. During the first few weeks in my new job I assembled an extensive bibliography on CPA and visited the laboratories of Prof. W. N. Lipscomb and Prof. B. L. Vallee at Harvard to obtain first-hand information on CPA. However, before I was ready to start experiments, a Varian HR-220 high-resolution ^1H NMR spectrometer operating at 220 MHz was delivered to our department. I was given responsibility for its maintenance, and in this easy and painless way I was out of relaxation enhancement experiments (see below) and into 'high-resolution NMR'. Fortunately, contacts with Bert Vallee and Bill Lipscomb survived my involvement with CPA, and have continued in most amiable ways over all these years.

HIGH-RESOLUTION NMR WITH BIOLOGICAL MACROMOLECULES IN 1967

A report by Saunders et al.¹ in 1957 which presented a 40 MHz ^1H NMR spectrum of ribonuclease A is the uncontested first paper on high-resolution NMR of a protein, soon to be followed by an interpretation of this spectrum by Jardetzky and Jardetzky.² During the following decade, one notes the publication of four papers on the ^1H NMR spectra of amino acids and linear oligopeptides, and 16 papers with ^1H NMR spectra of the proteins ribonuclease A, lysozyme, chymotrypsinogen, and cytochrome *c*. In this context, 'high-resolution NMR' refers exclusively to the fact that the resonance lines of the macromolecule were observed directly; inspection of the spectra makes it clear that there could not be any other implications!

When I entered the field in 1967, these early papers relayed two principal messages. One was simply the information on the approximate ^1H chemical shifts of the common amino acid residues obtained from studies of amino acids and oligopeptides. The second was the notion of the dispersion of the ^1H chemical shifts in folded polypeptide chains, which gradually evolved in papers by Kowalsky^{3,4} and Mandel,⁵ was evident in the data on the histidyl residues in ribonuclease by

Bradbury and Scheraga⁶ and by O. Jardetzky's group,⁷ and was clearly spelled out in an important paper by McDonald and Phillips.⁸ The chemical shifts of a limited number of well-separated lines were the only spectral parameters that could be measured reliably at the time, since scalar spin-spin couplings were not resolved even in the ^1H NMR spectra of small proteins. The ideas of 'ring current shifts'^{3,8} and 'electron delocalization near paramagnetic centers'⁴ giving rise to separated lines in unusual chemical shift positions thus provided an initial rationale for the appearance of protein ^1H NMR spectra.

MY RESEARCH EXPERIENCE UP TO 1967

From the days in the 'Gymnasium' my mind was set on a career in sports and physical education. While recovering from injury occasioned by pursuit of this goal, I nonetheless graduated in physics, mathematics, and chemistry at the University of Bern. Being fit again, I moved to the University of Basel in April 1962 for a formal education in sport as a full-time student for the 'Eidgenössisches Sportlehrerdiplom'. With the kind permission of Prof. Silvio Fallab, I started in October 1962 to spend the evenings doing some research in the Institute of Inorganic Chemistry. Shortly thereafter, Peter Hemmerich, then a young Privatdozent, organized a symposium on biological applications of EPR with the participation of, among others, A. Ehrenberg, H. Beinert, B.G. Malmström, and T. Vanngard. This was my first contact with magnetic resonance. I was fascinated by the fact that one could focus on novel features of metal centers in proteins without interference from the much larger polypeptide chains, and shortly thereafter I found myself in the laboratory of Prof. Peter Diehl in the Physics Institute. He was on sabbatical leave and had left an idle Varian V4501 state-of-the-art EPR spectrometer behind. I received the necessary training in the practice of EPR from Dr. Hans Loeliger, a physicist at Ciba AG who had previously used what was now to be 'my' EPR spectrometer. Some successful experiments with copper complexes that catalyze autoxidation reactions of aromatic amines⁹ led to my obtaining a Ph.D. in chemistry and the Sportlehrerdiplom in March 1964.

After spending another year in Basel, teaching high school sports and studying a variety of VO^{2+} complexes with the use of EPR,¹⁰ I joined Prof. Robert E. Connick at the University of California in Berkeley. I continued the studies with VO^{2+} complexes that I had started in Basel, adding ^{17}O , ^1H , and ^2H NMR relaxation enhancement studies to EPR. However much of the time was actually spent solving the problems in M. Tinkham's 'Group Theory and Quantum Mechanics' and recalculating, page for page, large portions of the monographs by A. Abragam and by C. P. Slichter for presentation in the group seminars. It is also worthwhile mentioning that with much help from Dr. Alfred Bauder from the ETH Zürich, who spent a sabbatical in Berkeley, a digital recording device for quantitative analysis of EPR difference spectra was installed. This must have been one of the really early such data handling setups, which contributed significantly to the eventual success of a project on studies of the hydration of VO^{2+} complexes.¹¹ Overall, while Prof. Fallab and his colleagues in Basel had awakened my interest for oxygen-binding and electron-transferring metalloproteins, Bob Connick and the

Berkeley environment provided me with a thorough basis in the theoretical aspects of both metal complexes per se and the more specialized field of electron and nuclear spin relaxation in metal compounds.

EARLY SURVIVAL WITH PROTEIN NMR

With hindsight, it is clear that there was little to be gained by using NMR for studies of proteins in the late 1960s. The more sophisticated NMR instrumentation at the time operated at ^1H frequencies of 60–100 MHz, and the only commercial high-field apparatus, the Varian HR-220, was a field-sweep, protons-only CW spectrometer. There was no field/frequency lock. For paramagnetic compounds the resonances of the center band and two to four sidebands would overlap, since the instrument used a 10 KHz field modulation with the first upfield sideband as the observation frequency.¹² For spin decoupling or other INDOR experiments, we used additional, home-built audio modulation of the observation frequency with the exact difference frequency between the presumed interacting spins, and then performed a field sweep through resonance. For signal averaging we interfaced a Fabritek computer (later to become Nicolet) with the NMR spectrometer, which provided us with rapid accumulation into 4 K of memory. However, for many applications the improved digital resolution (when compared with standard equipment in 1968) was of questionable merit, considering that there was no field/frequency lock. The need for sample spinning at 120–140 rps presented an additional risk for experiments with long accumulation times. Not surprisingly, for a detailed study of bicyclobutane, which is the only NMR at high resolution that I got involved in at the time, we relied mostly on a Varian HA-100 spectrometer.¹³

Other than the above-mentioned study of bicyclobutane,¹³ all my projects at Bell Labs had to do with hemoproteins. Due to my background, my interest was focused on metal centers rather than polypeptide chains. Thus, in the seminal paper by McDonald and Phillips⁸ I was intrigued by a description of NMR spectral differences between the reduced, diamagnetic state and the oxidized, paramagnetic form of cytochrome *c*; based on my earlier work with Bob Connick, this seemed to present novel perspectives. Fortunately, a collaboration on myoglobin was established with Dr. Jack Peisach, Prof. Emanuel Margoliash kindly supplied me with various cytochromes *c* and for many years with expert advice on this class of proteins, and Dr. Tetsuo Yamane at Bell Labs. prepared hemoglobin KW, using blood sampled from my arm in the first aid station. Within a few months, numerous well-separated resonance lines arising from electron–proton contact and pseudocontact coupling, and from interactions with the porphyrin ring current field were identified in the ^1H NMR spectra of all these proteins. This opened new avenues to information on the molecular structure, e.g. in cytochrome *c*,¹² on conformation changes during the oxygenation of myoglobin and hemoglobin,¹⁴ and on the electronic structure of the heme group.¹⁵ Some lucky circumstances ensured rapid acceptance of these results. At the ENC in Pittsburgh in the spring of 1988, Oleg Jardetzky graciously added an unscheduled 5 min presentation of my data to the program of his symposium on biological NMR. Sir Arnold Burgen was in the audience and, as I learned later on, relayed the information on the

hemoglobin studies to Dr. M. Perutz. Dr. Perutz immediately called to announce a visit at Bell Labs, to get first-hand information. Clearly, my day was made and support for the continuation of the work ensured. A review of this early work¹⁵ was accepted as the ‘Habilitationsschrift’ by the ETH Zürich in 1969, and later on became a Citation Classic, reflecting that work in this area has continued during all these years and is still going on.

At the ETH Zürich, where I moved in October 1969, a Varian HR-220 instrument had already been set up. Due to the proximity of the streetcars running with direct current, the absence of an effective field/frequency lock was a disaster for anyone attempting to work at high resolution (see *Ernst, Richard R.: The Success Story of Fourier Transformation in NMR*), and it did not help that the only data acquisition device available was a Varian CAT with 1 K of memory. However, in hemoproteins the lines of interest were so broad that neither the streetcars nor the low digital resolution presented serious obstacles. Fortunately, I had brought some sample tubes with me that enabled spinning at the required rate of about 120 rps, which apparently had not been achieved previously with the Zürich instrument (only 2–5 out of 100 of the highest-grade tubes then available could be used). As a matter of fact, the unfortunate situation was to my advantage. Although the HR-220 was to be shared equally among five institutes, I was soon encouraged to use most of the measuring time available. Critical measurements had to be made between midnight and 5 a.m., which soon became a routine.

In 1970, we obtained a Varian XL-100 multinuclear MR spectrometer capable of CW and FT operation. Although it was used for some aspects of the hemoprotein projects, e.g. ^{13}C NMR of metalloporphyrin complexes¹⁶ and studies of high-spin ferrous hemoproteins,¹⁷ this instrument primarily enabled us to embark on new projects with synthetic oligo- and polypeptides. In collaboration with Prof. Robert Schwyzer, some encouraging results were obtained with proline-containing cyclopentapeptides, where equilibria between multiple conformations containing *cis* and *trans* Xxx–Pro peptide bonds were characterized.¹⁸ Overall, this and other successful studies at this field strength were mostly achieved with ^{13}C NMR in dimethylsulfoxide and other non-aqueous solvents. To obtain a more reliable basis for such work, 20 peptides TFA–Gly–Gly–Xxx–Ala–OMe₃ where Xxx represents one of the 20 common amino acid residues, were custom made for us by Bachem AG for the collection of ^{13}C reference shifts.¹⁹

By 1971 I had assembled my first research group. It included Dr. Regula Keller, who had obtained her Ph.D. in solid state physics undertaking EPR spectroscopy with Prof. Werner Känzig at the ETH. Regula’s early work on a variety of cytochromes²⁰ and oxygen-binding proteins,²¹ and on the determination of the electronic *g*-tensor in ferricytochrome *b*₅ from the ^1H hyperfine shifts,²² started a collaboration that continued for more than a decade. Rudolf Baumann is a chemical engineer who was involved in many of the early research projects¹⁶ and has over all these years been responsible for much of the functioning of the laboratory. The first two graduate students were Jean-Paul Meraldi, who worked with cyclopeptides, and André Masson, whose work will be mentioned below. They were joined in 1972 by Christoph Grathwohl,¹⁹ Jiri Hochmann¹⁷ and Robert Hetzel, who was the first theoretical physicist in the group and initially

worked on ring-closure conditions for cyclic peptides, and in 1973 by Arno Bundi and Gerhard Wagner.

As I felt that we were not in a position to compete with the leading groups abroad, I established a policy of keeping our hands off ribonuclease, staphylococcal nuclease, and lysozyme, a rule which was strictly followed over all these years. We thus had to look around for other polypeptides and proteins that would be suitable for NMR studies. After a long line of inconclusive experiments with polypeptide hormones such as calcitonin and ACTH, Andre Masson's thesis was saved by the discovery of numerous well-resolved resonance lines from slowly exchanging amide protons in the protein BPTI.²³ BPTI subsequently became so central to our research that I was asked to write a special section on this protein for this Encyclopedia (*Pancreatic Trypsin Inhibitor*).

Gerhard Wagner joined us as a graduate student to work on the crystal field theory of hemoproteins, which would have been in line with his diploma thesis in Mössbauer spectroscopy at the TH München, but I convinced him to perform a detailed analysis of the aromatic region of the ¹H NMR spectrum of BPTI 'on the side.' We soon became stuck because careful integration yielded the intensity of 30–32 rather than the expected 36 aromatic protons at temperatures from 20–50 °C. After pondering over this for a while, we decided to present this result at the 6th International Conference on Magnetic Resonance in Biological Systems, in Kandersteg in September 1974, where we heard in the discussion that another group had obtained proper integration to 36 protons at the same temperatures (this was never published). One evening I discussed this curiosity over dinner with Prof. Zeev Luz, who spent some time with us following the Kandersteg meeting. He strongly encouraged me to continue the search for dynamic phenomena. Several weeks later we had obtained very direct, quantitative evidence for ring-flipping motions of Phe and Tyr by extending the NMR measurements to a wider temperature range.²⁴ This result was unexpected because it appeared to contradict the temperature factors measured for the ring carbon atoms in the BPTI crystal structure. However, model calculations that Robert Hetzel performed, in collaboration with Dr. Johannes Deisenhofer during a stay in Prof. Robert Huber's laboratory in Munich, cleared up this apparent discrepancy.²⁵ The discovery of the ring flips in BPTI in October 1974 probably did more than any other single result to make our existence known to others in structural biology. It came at the end of the first phase of my activity in Zürich during which I had worked quietly with a small group of students, Dr. Regula Keller and Rudolf Baumann, spending much of my time in the laboratory.

1975–76—AN INTERLUDE

The publications from this period show that we obtained more precise data on hemoproteins, oligopeptides, and internal mobility in proteins while further pursuing the projects of the preceding years. Noteworthy are the introduction of the sine-bell for digital filtering²⁶ and the fact that several papers described nonrandom conformations for linear oligopeptides.^{27,28} Most importantly, however, during those two years my research group was more comfortably installed and critical decisions were made for the future.

The technical difficulties mentioned above with the operation of the HR-220 instrument in Richard Ernst's laboratory, and the fact that as a consequence we became the dominant user of the facility, led to the decision to install a Bruker HX-360 multinuclear FT spectrometer in my laboratory. For the first time we could embark on high-field experiments going beyond simple chemical shift measurements. Simply repeating selected experiments of the previous years provided a wealth of new results, since the step from 100 MHz to 360 MHz was really revolutionary, and important improvements had also been made in the data-handling facilities. Although outside users of the 'high-field NMR facility for the ETH and the University of Zürich' were entitled to two days per week of measuring time, it was really 'our' instrument on which we could work continuously on technical improvements. In this way, a most fruitful collaboration with Bruker-Spectrospin AG developed, and has continued over all these years. Attached to the 'high-field NMR facility' was a permanent position for an engineer, which was held first by Alexandra Frey, then for a decade by Albert Eugster, and now by Daniel Braun, all of whom have done a great job in keeping the laboratory up and going. This was a big change, since my entire research group had previously been on soft money. Shortly thereafter, the ETH made a major commitment by allotting permanent positions for additional scientific associates and engineers as well as a secretary, and by increasing our laboratory space severalfold. Another important change came about by the fact that, for the first time, the group was joined by postdoctoral associates with previous NMR experience, i.e. Larry Brown, Antonio DeMarco, Miguel Llinás, and Stephen Perkins, as well as academic guests specialized in biochemistry and other disciplines related to our work, i.e., Joseph Gilboa, Jürgen Lauterwein, Klaus Loth, Lea Stassinopoulou, and Vincenza Viti. This changed the character of the group in dramatic ways, greatly widened the scope of our activities, and helped to open the eyes of local students to the outside world.

For me personally, organizing (jointly with Richard Ernst and Joachim Seelig) the biennial International Conference on Magnetic Resonance in Biological Systems in Kandersteg in 1974, writing a monograph on 'NMR in Biological Research: Peptides and Proteins'²⁹ in 1975, and experience gained when serving as a member of the then structural biology-oriented council of IUPAB greatly helped to clarify some issues. I realized that we could only attain broader acceptance by the biochemistry community if we worked with a technique capable of de novo determination of molecular structures, other spectroscopic data alone being too difficult to explain or visualize for easy communication. However, a thorough survey of the then available literature of about 500 titles, which was part of the preparation for writing the book, showed that despite some admirable individual efforts there was no existing line of NMR work with polypeptides that could lead to this goal. The literature did not even contain an attempt at determining a previously unknown polypeptide fold on the basis of NMR data. In practice, structural information from X-ray crystallography, and in some instances from a knowledge of the restricted conformational space for cyclic peptides, was typically used as a basis for obtaining resonance assignments and for rationalizing experimental NMR parameters.

This was important groundwork and the field probably had to go through this phase. However, the fact that some unusual ¹H chemical shifts could be interpreted on the basis

of protein crystal structures and used for qualitative studies of conformational transitions²⁹ resulted in the widespread misconception that ^1H chemical shifts would eventually provide a basis for de novo structure determination. As a major gain from the effort of working through the available literature, I convinced myself at the time that the local fields which give rise to conformation-dependent shifts, such as ring-current fields, fields near peptide groups, and pseudocontact fields near paramagnetic centers, would, because of their high intrinsic symmetry not be suitable for delineating novel, previously unknown structures. In contrast to the rather disappointing role perceived for NMR in the area of structure determination, the technique had clearly made seminal contributions to the investigation of dynamic features in proteins and to studies of amide proton exchange. However, by 1975, the phenomenon of internal mobility in proteins and the ability to measure exchange kinetics for individual amide protons had been well documented, and further characterization of protein mobility could only be achieved on the basis of additional information on resonance assignments. Similarly, it was clear that further progress with studies of paramagnetic centers in metalloproteins would depend on the additional availability of individual resonance assignments.

Research proposals submitted at the time show that I ended up with three crucial decisions during those two years. Firstly, a research project was submitted that envisaged developing techniques for obtaining resonance assignments in proteins entirely on the basis of spectroscopic data and covalent structure. Secondly, jointly with Richard Ernst, a project to develop 2D NMR techniques for studies of proteins was submitted. Thirdly, I joined a group of colleagues in mathematics and computational sciences to establish the 'Zentrum für Interaktives Rechnen' at the ETH Zürich. From 1977 onward we thus had access to computer graphics facilities for theoretical work with proteins and visualization of our hoped-for results on novel molecular structures.

STUDIES WITH OLIGOPEPTIDES

For some time each newcomer to the group had to start by fully analyzing the 100 MHz ^1H NMR spectra of several linear model tetrapeptides, i.e. TFA-Gly-Gly-Xxx-Ala-OMe.³⁰ With the availability of the 360 MHz spectrometer it soon became apparent that more precise reference chemical shifts were also needed for aqueous solutions. Hence, René Richarz, who joined the group as a graduate student in 1976, and Arno Bundi measured the 'random coil' ^{13}C shifts³¹ and ^1H shifts³² of the common amino acid residues Xxx in aqueous solutions of the 20 peptides H-Gly-Gly-Xxx-Ala-OH, which also provided evidence for nonrandom conformational features of these linear oligopeptides. Most notable is the transient formation of amide proton-carboxylate hydrogen bonds,³³ which has also been observed subsequently on the surface of numerous globular proteins. Overall, in addition to the widely used reference chemical shifts, studies of these peptides provided reference data for conformational studies of flexible regions in proteins based on amide proton titration shifts³³ and the observation of *cis-trans* isomerism of Xxx-Pro peptide bonds.²⁸ Miguel Llinás and Antonio DeMarco performed a series of beautiful homonuclear and heteronuclear experiments with ^{15}N - and ^{13}C -labeled aluminichrome. Although primarily

designed for obtaining more detailed insights into the structural and dynamic properties of ferrichromes, these measurements provided important reference data on the calibration of Karplus-type relationships for $^3J_{\alpha\beta}$,³⁴ $^3J_{\text{HN}\alpha}$,³⁵ and $^3J_{15\text{N}\beta}$.³⁶

^1H - ^1H NOEs AND SPIN DIFFUSION

Although heteronuclear NOEs had been used routinely to enhance the signal intensity for the direct observation of ^{13}C or ^{15}N and had also been applied for studies of segmental mobility in proteins, homonuclear ^1H - ^1H NOEs had generated little enthusiasm by 1976. The following quotation from the only monograph on the subject at the time explains some of the reasons for this:³⁷ 'However, the numerous existing books on NMR written primarily for chemists barely mention the NOE and do not provide the background in nuclear relaxation theory necessary to understand it. Aside from original research papers, only a few references of a highly theoretical nature are extant. The difficulty and rigor of these references has been a source of frequent misunderstandings and has surely limited the growth of the field'. During the period 1970-75 the laboratories of A. G. Redfield, A. A. Bothner-By, and I. D. Campbell had published short reports on the observation of ^1H - ^1H NOEs in proteins, and W. A. Gibbons and his colleagues had used INDOR experiments to observe NOEs in peptides. In 1976, Kalk and Berendsen³⁸ presented a reevaluation of the classical treatments of spin relaxation in Solomon's 1955 paper and Abragam's book, concluding with a pessimistic outlook regarding selective NOEs in proteins because of the expected dominant effects from spin diffusion. As one of several different approaches to obtaining resonance assignments (see below), we nonetheless decided to investigate the potentialities of our new 360 MHz instrument for NOE studies, with the result that NMR with biological macromolecules was never quite the same again for us.

Hemoproteins once again turned out to be a lucky choice for the initial NOE experiments. The ^1H NMR spectrum of diamagnetic ferrocytochrome *c* contains well-separated resonance lines of the axial methionyl ligand of the heme iron at high field between -4 ppm and -1 ppm, and at around 10 ppm there are the equally well-separated lines of the four *meso*-protons of the heme group.^{12,15} Within a short space of time 1D NOE experiments with irradiation of these well-resolved lines yielded strong, selective negative NOEs. We could thus perform all the studies on the spin physics in the molecular core of a globular protein that would become accessible for other proteins only many years later with the use of 2D NOESY. Regula Keller soon completed a 'sequential NOE walk' around the periphery of the heme group, and the individual resonance assignments thus obtained for reduced cytochrome *c* were extended to the paramagnetic, oxidized protein using magnetization transfer mediated by the electron exchange between the ferrous and ferric states.³⁹ This was a crucial advance in the characterization of the electronic structure of low-spin ferric hemes, which opened an avenue for investigations of evolutionary changes in heme structure by Regula Keller and a new graduate student, Hans Senn.⁴⁰⁻⁴² René Richarz optimized NOE difference spectroscopy in ways that served us well for several years.⁴³ In 1977, Prof. Sidney Gordon joined the group to spend a sabbatical year. Combination of his long-standing experience in NOE

spectroscopy with the current state of our work resulted in the 1D transient NOE experiment and the first recordings of NOE build-up curves.⁴⁴ Although 1D applications were for technical reasons more limited for transient NOE measurements than for conventional preirradiation techniques,³⁷ these results had a fundamental impact on our work, not to speak of the fact that the 1D transient NOE experiment contains all the elements of 2D NOESY except for the evolution period (see below). Since transient NOE measurements enabled us to follow the time course of the nonequilibrium magnetization on numerous individually assigned spins in the absence of radiofrequency irradiation, we soon identified the main reason for the success of our 'steady-state' experiments: the preirradiation times had been optimized such that the systems never actually reached the steady state. Gerhard Wagner optimized the use of the preirradiation technique with the 'truncated driven NOE experiment' (TOE),⁴⁵ and we checked carefully that coincident information was obtained from TOEs and transient NOEs.⁴⁶ The TOE experiment was used extensively until it was replaced by 2D NOESY.

By late 1977 it was clear from the experiments mentioned above that ^1H – ^1H NOEs would not only help to obtain improved spectral resolution and resonance assignments,^{39,43,46,47} but that despite spin diffusion³⁸ it was a parameter that provided the type of information needed for de novo three-dimensional protein structure determination. Initial success in obtaining novel structural data was achieved for the heme crevice in hemoproteins. Because individual ^1H NMR assignments for the heme groups had been based exclusively on NMR data and the covalent structure of the porphyrin ring,³⁹ NOE experiments revealed that the previously mentioned evolutionary change of the electronic heme structure in *c*-type cytochromes was related to a change in the chirality of the axially bound methionyl residue.^{41,48} The orientation of the heme group relative to the folded polypeptide chain in cytochrome *b*₅ as described in the crystal structure was revised,⁴⁹ and dynamic equilibria between multiple different heme orientations in reconstituted cytochromes *b*₅ and *b*₂ were identified and characterized structurally.⁴⁷

SEQUENTIAL RESONANCE ASSIGNMENTS

In 1976–77, we tested a wide range of approaches for obtaining resonance assignments with or without reference to the three-dimensional protein structure. This included ^1H spin system identifications for amino acid side chains using spin decoupling, ^{13}C – ^1H chemical shift correlation, ^1H chemical shift correlation between the native and denatured forms of the protein, interpretation of NOEs based on the protein crystal structure, and comparison of mutant and chemically modified proteins. Stephen Perkins, a postdoctoral fellow who had joined us from Oxford, applied ring-current calculations and paramagnetic shift reagents with BPTI.^{50,51} However, the key experience during those two years was Regula Keller's 'sequential NOE walk' around the periphery of the heme group in hemoproteins³⁹ (see the preceding section). In March 1978 a young physicist, Andreas Dubs, joined Gerhard Wagner and myself for his diploma thesis, and within a few months had performed a corresponding sequential assignment walk along the strands of the β -sheet in BPTI.⁴⁶ The results also included interstrand NOEs, showing that the structure of multistranded

β -sheets in proteins could be determined with the techniques used. Although the project started with frequent reference to the BPTI crystal structure, it soon became clear that the method could yield sequence-specific assignments without previous knowledge of the three-dimensional structure, and in the Discussion section of the paper we also proposed the determination of new amino acid sequences using the sequential assignment approach.

After obtaining his ETH diploma, Andreas Dubs left for Australia, and to the best of my knowledge never again touched an NMR spectrometer. For those of us who stayed behind, his contribution gave a clear direction for the further development of assignment techniques, which were from this point on entirely focused on the use of spectroscopic methods for spin system identification and establishing sequential connectivities between the spin systems of individual amino acid residues. The sequential assignment approach using 1D NMR yielded partial assignments in several additional polypeptides and proteins. In 1980, using independently developed 2D NMR experiments (see below), the assignments of Andreas Dubs⁴⁶ were extended to molecular areas of BPTI outside of the β -sheet.^{52,53} With the use of a newly arrived Bruker WM-500 spectrometer operating at 500 MHz, complete assignments of BPTI were eventually obtained in 1981. Two new graduate students, Martin Billeter and Gerhard Wider, and Dr. Kong-Hung Lee had by that time joined the assignment project. A series of four papers in 1982 presented an outline of the NMR method for protein structure determination in solution,⁵⁴ the theoretical basis of the sequential assignment approach,⁵⁵ and complete assignments for BPTI⁵⁶ and micelle-bound glucagon.⁵⁷

In 1981–82, a group of highly gifted postdoctoral fellows joined the group for work on protein structure determination—Alexandr Arseniev, Françoise Guerlesquin, Ramakrishna Hosur, Dominique Marion, David Neuhaus, Arthur Pardi, Lea Stassinopoulou, Petr Štřop, Michael Williamson, and Eric Zuiderweg. Within two years we obtained sequence-specific assignments for a half-dozen small proteins, which confirmed that the method was generally applicable. Some results were of special interest for the further development of the methodology. Eric Zuiderweg brought the *lac* repressor DNA-binding domain from Robert Kaptein's laboratory to Zürich, and we obtained complete resonance assignments⁵⁸ and determined the secondary structure of the *lac* headpiece⁵⁹ in my laboratory in Zürich, thus demonstrating the use of the assignment method with an α -protein. With bull seminal proteinase inhibitor (BUSI),⁶⁰ a protein brought to Zürich from Prague by Petr Štřop, and rabbit metallothionein,⁶¹ a protein investigated in collaboration with Prof. Jeremias Kägi at the University of Zürich, the sequential NMR assignments led to the identification and correction of numerous errors in the chemically determined amino acid sequences. In 1983, metallothionein was also the first protein where we combined the sequential assignment technique with isotope labeling to achieve the desired result.⁶²

Overall, during the period 1982–94, we determined complete sequence-specific assignments for more than 40 proteins and complexes of proteins with DNA and other ligands, using the method based on sequential NOEs. In complex systems this sequential assignment approach was supported by selective or uniform isotope labeling,⁶³ which also enabled complete assignments for a urea-unfolded protein.⁶⁴ In addition, special

labeling techniques were developed for obtaining stereospecific assignments.⁶⁵ In recent years much effort has gone into software development for computer support of the resonance assignments, with important contributions by Craig Eccles, a postdoctoral fellow from New Zealand, Martin Billeter and two graduate students, Peter Güntert and Christian Bartels.⁶⁶ It has also been a great pleasure to see the assignment field evolve in recent years with alternative sequential approaches developed by others, thus benefitting our own work via these additional techniques.

DETERMINATION OF THREE-DIMENSIONAL NMR STRUCTURES OF PROTEINS

As mentioned previously, we obtained access to modern computer graphics equipment for theoretical studies of proteins in 1977. During the following years up to 1984, two postdoctoral fellows, Werner Braun and Timothy Havel, and a graduate student, Martin Billeter, did a great job using these facilities so that we would be prepared to perform structure determinations once the necessary NMR data became available. We also received valuable outside advice from Prof. Nobuhiro Gō, who spent three months with us as a visiting professor in 1979, and from Prof. Max Engeli of the ETH, an expert in information theory and computer graphics who codirected the Ph.D. thesis of Martin Billeter. Based on what we had learned from NOE build-up measurements, the projects were soon focused on structure determination from qualitative NOE upper distance constraints. These could take account of internal molecular mobility and would be robust relative to possible errors in NOE intensity measurements. Further, it was important to us that the interpretation of the NMR data should be clearly separated from theoretical refinement routines. There was no software available that could be used for our purposes and even basic routines for graphics displays, for example, had to be written. This situation forced us to become heavily involved in software development, which has been an important part of our activities ever since. Three different approaches at different levels of structure determination proved to be of practical use.

Statistical analyses of the small collection of high-resolution protein crystal structures available in 1980 provided not only a basis for the sequential assignments with NOEs,⁵⁵ but in addition led to a pattern recognition approach for the identification of regular secondary structures and turns in polypeptides.^{67–69} The data collection for resonance assignments based on sequential NOEs supplemented with measurements of amide proton exchange rates thus turned out to be sufficient also for secondary structure identification. In contrast to crystallographic protein structure determination, where the sequence locations of secondary structure elements are one of the last features to evolve, the secondary structures in solution are thus obtained at an early stage of an NMR structure determination. Subsequently, this fact has been used to support crystallographic chain tracings with secondary structures determined by NMR.⁷⁰

As a second approach, Martin Billeter wrote the program CONFOR,⁷¹ which enabled the generation of different conformations of large molecular structures by real-time variation of the torsion angles. A fit to NOE distance constraints was

interactively achieved by minimizing constraint violations displayed in the molecular structure on the graphics screen. An early success with the use of CONFOR was the determination of the three-dimensional chain fold of the *lac* repressor DNA-binding domain.⁷² The *lac* repressor structure was subsequently refined many times, mainly by Robert Kaptein and his colleagues, but the molecular architecture of 1984⁷² has stood the test of additional data collection and more sophisticated computational procedures. Although other programs soon proved more efficient for the determination of complete protein structures, CONFOR served us well for many years, both for interactive local structure refinement and for the visual presentation of the NMR structures.

The third approach was distance geometry in metric matrix space. Initially, Prof. Gordon Crippen kindly provided a software package that was in use in the San Francisco group at the time. Werner Braun then developed a first distance geometry package suitable for structure determination from NMR data, which included complete covalent amino acid structures with proper chirality so that the handedness of the resulting molecular geometries could be unambiguously assessed. Because of the high demands for computing capacity, the application of this program was limited to polypeptides with up to about 10 residues. Using this software and data collected with 1D NMR experiments by Larry Brown and Chris Bösch, a physics graduate student who went on to an M.D. and a successful career in medical NMR, we had gone through all the steps of an NMR structure determination even by 1980, with an application to a 10-residue segment of the polypeptide hormone, glucagon.⁷³ A complete structure of micelle-bound glucagon based on 2D NMR data collection and structure calculations for overlapping 10-residue segments was obtained in 1983.⁷⁴ At this time we also developed a pseudoatom concept for dealing with prochiral centers in the absence of individual assignments for the diastereotopic substituents.⁷⁵ Werner Braun left the project in 1982, and Tim Havel took over and wrote the new software package DISGEO.⁷⁶ To overcome the limitations imposed by the available computing facilities, DISGEO used an original substructure description of polypeptide chains in the early phases of the calculations. With continuous use of more than 50% of the capacity of the 'Zentrum für interaktives Rechnen' and heroics on Tim's part in making optimal use of the computer facilities, extensive test calculations confirmed that complete globular protein structures could be determined by NMR.⁷⁷ Using input data collected by Michael Williamson, the first de novo structure determination of a globular protein, BUSI, was completed in March 1984.⁷⁸ The program DISGEO was subsequently widely used worldwide in a large number of NMR structure determinations.

In 1984, Werner Braun rejoined the group after a postdoctoral stay with Professor N. Gō, where he had continued work on a distance geometry approach in torsion angle space that he had originally started in Zürich. From 1985–90 his program DISMAN was used in several important structure determinations, notably Tendamistat^{79,80} and metallothionein,⁸¹ and its performance was also compared in detail with that of DISGEO.⁸² A big advance then resulted from the work of Peter Güntert, who developed and implemented a wide array of new techniques for all aspects of efficient structure calculation and for dealing with prochiral centers; the most widely used to date are the programs HABAS⁸³ and DIANA,⁸⁴ and

the REDAC strategy.⁸⁵ Since 1985, NMR structure calculation has evolved into an exciting, lively field with a variety of different approaches which have also influenced our work, for example, in relaxation matrix refinement of NMR structures,⁸⁶ novel strategies for structure calculation of multimolecular complexes with proteins,⁸⁷ and in many aspects of structure refinement.⁸⁸ Thomas Schaumann, Tai-he Xia, and Berthold Freiherr von Freyberg made important contributions in these areas while getting their Ph.D. degrees in theoretical physics.

ESTABLISHING CREDIBILITY FOR NMR STRUCTURES OF PROTEINS

When I presented the NMR structure of BUSI^{78,89} in some lectures in the spring of 1984, the reaction was one of disbelief and suggestions that our structure must have been modeled after the crystal structure of a homologous protein. In the discussion following a seminar in Munich on May 14, 1984, Robert Huber proposed that the matter be settled by the independent determination of a new protein structure in his laboratory by X-ray crystallography and in my laboratory by NMR. Each of us received 100 g (!) of pure Tendamistat from Dr. L. Vértessy at Hoechst AG and, as is well documented in the literature,^{79,80,90–93} this project was started. Dr. Allen Kline had arrived in Zürich in March 1984 and agreed to join the competition. We obtained complete resonance assignments and the secondary structure determination by the end of the summer 1984.⁹⁰ In late 1985, virtually identical three-dimensional structures had been obtained in solution⁷⁹ and in crystals.⁹¹ Some editorials then caused many to believe that Tendamistat, rather than the earlier work by Tim Havel and Michael Williamson with BUSI,⁷⁸ was the first complete *de novo* NMR structure determination of a globular protein. The fact that a genuinely novel type of polypeptide fold had been determined in the NMR structure of Tendamistat⁷⁹ apparently convinced many of the critics that NMR could actually do the job.

The Tendamistat experience was comforting when we came out with the structure determination of rabbit metallothionein in the spring of 1985.⁹⁴ In response to the first public presentations of this structure at Yale University on June 10 and at the University of Pittsburgh on June 12, I was confronted with a crystal structure of rat metallothionein that was very different from our NMR structure. Early on June 13, I spent several hours on the telephone with Gerhard Wagner to start rechecking our data, a process that was continued for several weeks after my return to Zürich. I am afraid that Gerhard never forgave me for ever harboring doubts about our results at this point and putting him through this painful procedure again (with metallothionein we were at the limits of the techniques available in 1985, and we had previously gone through several tedious rounds of checks on the resonance assignments). Soon thereafter we showed that the NMR structures of three homologous metallothioneins from rabbit, rat, and man are virtually identical, and several years later the crystal structure of rat metallothionein was redetermined and found to coincide actually very closely with our NMR structure.⁹⁵

One consequence of all this was that publication of the initial papers on BUSI,⁷⁸ Tendamistat,⁹⁰ and metallothionein⁹⁴ was delayed by many months in each case, because we faced rejection on a variety of grounds. On a more joyful note, I felt

more and more compelled to document our work more carefully in a monograph.⁶⁹ To this end I took a sabbatical in the beautiful alpine resort of Wengen, where I eventually spent two winters and made up for the skiing that I had missed during the past two decades. Since 1985, numerous new polypeptide folds have been determined by many different NMR laboratories. During 1992 alone, more than 50 new NMR structures of biological macromolecules were reported,⁹⁶ and these are now routinely deposited in data banks jointly with the X-ray crystal structures.

INTRODUCING MULTIDIMENSIONAL NMR TO STRUCTURAL BIOLOGY

In joint projects between Richard Ernst and myself during the period from November 1976 to April 1987, multidimensional NMR techniques were developed to the stage where they could be applied for studies of biological macromolecules. Over these 10 years we had a continuous line of highly gifted postdoctoral fellows working with us. During the initial three-year period, Kuniaki Nagayama was employed full time and Peter Bachmann half-time on the project. Their successors were, in chronological order, Anil Kumar, Slobodan Macura, Mark Rance, Michael Frey, Norbert Müller, and David Redwine. The arrangements were that the postdoctoral associate was stationed in my laboratory on the Hönggerberg campus of the ETH, with the sole exception of Peter Bachmann who was stationed in Richard Ernst's laboratory on the main campus, a distance of about 10 km away. The postdoctoral associates would participate in the research seminars of both groups, all the experimental work was done in my laboratory, and Richard Ernst and I would meet with our research associate at monthly intervals, or more often when required by the course of the work. From 1976–79, the project lived on the solid professionalism of Peter Bachmann in developing software for NMR spectroscopy, the heroics of Kuniaki Nagayama in realizing things on the computer and in the laboratory, and the intense personal involvement of Richard Ernst and myself. Otherwise it was low key and was hardly noticed by other members of my research group, who were mostly working with 1D NOE experiments. This situation changed once Kuniaki Nagayama had demonstrated the practical application of correlation spectroscopy for spin system identification in a protein,⁵² and Anil Kumar made the best possible use of two weeks of instrument time allotted to him during the Christmas break of 1979 by recording the first 2D NOESY spectra.⁹⁷ At around this time the acronyms SECSY, FOCYSY, NOESY, and COSY were coined (I learned only very recently that my old friend George Feher had previously used 'COSY' for 'optical correlation spectroscopy'),⁹⁸ and my entire group started to use 2D experiments on a daily basis. Experience from more than a decade of NMR with proteins was thus linked with the new technique, which resulted in further rapid progress. The first major steps were to record homonuclear 2D data sets in aqueous solution⁹⁹ and to repeat the NOE buildup studies originally performed with the 1D transient NOE experiment⁴⁴ with 2D NOESY.¹⁰⁰ The projects were thereafter largely formulated on the basis of needs arising from our daily work with biological molecules, and since contacts with practical life were ensured, new techniques were often in general use in my group within weeks of the discovery.

We apparently used imaginary threats of imminent competition to impress our collaborators [see *Nagayama, Kuniaki: The First Protein Two-Dimensional (2D) NMR*]. However, it is actually remarkable (and clearly documented in the literature) that for nearly a full decade after our entry into the field, there was very little outside competition in multidimensional NMR with biological macromolecules. Clearly, our work was hardly considered to have too promising a future, as was also indicated by the fact that the first paper on this project¹⁰¹ was initially rejected during the refereeing process.

PLAYING THE GAME OF NMR IN STRUCTURAL BIOLOGY

The present account emphasizes method development, but I cannot end without mentioning that at each level of the evolving technologies our research was strongly focused on applications of biological interest. Projects with hemoproteins and oligopeptides have already been mentioned, as have the early results on protein dynamics. Once sequence-specific assignments became available, we mapped the internal mobility of the BPTI molecule on the timescales of chemical shifts as well as relaxation times,^{102–105} which also included high-pressure experiments. Gerhard Wagner had pursued this line of research during his Ph.D. thesis, and he also wrote a beautiful Habilitationsschrift on the subject. With regard to the protein-folding problem, the resonance assignments provided the basis for Heiner Roder's development of the now widely used amide proton trap experiment.¹⁰⁶ From 1985 onward, our projects concentrated primarily on structure determinations with proteins relating to a wide spectrum of biological problems, and with the participation of Dr. Arthur Pardi, Dr. Werner Leupin, and a graduate student from China, Mrs. Yan Qiu Qian, we also became involved in work with nucleic acids.^{107–118} Complementation of these structures with dynamic information became a focal point again with the introduction of techniques for the observation of hydration water molecules in 1989.^{119,120} During these years, NMR method development was pursued mainly when we became stuck with a structure determination. In this way, Gottfried Otting, first as a graduate student and then as an assistant, Gerhard Wider, who rejoined the group in 1987, and Thomas Szypersky, a graduate student and now an assistant in the group, made important contributions to heteronuclear filtering¹²¹ and higher-dimensional NMR.^{122,123}

Space does not permit me to give due credit to the achievements of all the postdoctoral fellows and graduate students who joined the group to work on structure determinations. In addition to the new biological insights gained from their work, their interactions with those involved in techniques development have been a vital element in the evolution of the methods used. I can only hope that this fruitful and exciting interplay of biological, biomedical, NMR technical and theoretical interests will also continue in the future.

Acknowledgements

The research projects mentioned in this article were generously supported by the ETH Zürich, the Schweizerischer Nationalfonds,

the Kommission zur Förderung der wissenschaftlichen Forschung, and Bruker-Spectrospin AG. I wish to thank Mrs. E. Huber and Mr. R. Marani for the careful processing of the manuscript. While writing this article I was a Fairchild Distinguished Scholar at the California Institute of Technology, and I would like to thank the Division of Biology and the Beckman Institute for their gracious hospitality.

Biographical Sketch

Kurt Wüthrich, *b* 1938. Licentiat, 1962, Physics, Mathematics, Chemistry, University of Bern; Eidgenössisches Sportlehrerdiplom, 1964, University of Basel, Ph.D., 1964, Inorganic Chemistry (Prof. S. Fallab) University of Basel. Postdoctoral work, University of Basel (Prof. S. Fallab), University of California, Berkeley (Prof. R. E. Connick), Bell Telephone Laboratories, Murray Hill, NJ (Dr. R.G. Shulman). Since 1969 at ETH Zürich, currently Professor of Biophysics and Chairman of the Department of Biology. Approx. 500 publications. Research specialties: NMR structure determination of biological macromolecules, drug design, and protein engineering.

Yannoni, Costantino S.: A Magnetic Resonance Potpourri

Costantino S. Yannoni

IBM Almaden Research Center, San Jose, CA, USA

PROLOGUE

Although I have devoted much time and energy to NMR, the rewards of working in the field have far exceeded the expectations I had 35 years ago as a graduate student, particularly because I did not expect to make so many good friends or to become part of a magnetic resonance ‘family’. So I want to start with an expression of gratitude to my colleagues, too numerous to mention all individually, who have taught me to do science and to grow personally over the years. In these respects, NMR encompasses a special community and I feel privileged to be part of it. And I would like to dedicate this narrative to Raffaella Yannoni for her unstinting love, encouragement, and support over the years.

GRADUATE WORK AT COLUMBIA (1960–66): FAILED AT SOLIDS, BAILED OUT BY LIQUID CRYSTALS

After a brief flirtation with physical organic chemistry, I chose to do my thesis in NMR with Ben Dailey. Rich Bersohn, who had just done calculations of the deuteron quadrupole coupling constant, suggested a measurement in perdeuteronaphthalene and Ben thought this would be a good thesis project. This required labeling the material and building a very low level fixed-frequency marginal oscillator to work with a 1.4 T electromagnet. In the early 1960s, Dailey students were doing high-resolution work without a field/frequency lock, using high-wattage light bulbs immersed in a tank of flowing tap water to control the magnet temperature, while nursing the magnet to high homogeneity over the course of weeks. So when I came along and twirled the fine-current dial to search for resonance over field ranges 100-times larger than they used, all hell would break loose. After building the oscillator and growing single crystals of perdeuteronaphthalene, I would come in first thing in the morning, see two lines separated by about the right splitting, and get nothing for the rest of the day. It turned out T_1 is in the order of hours and since I didn’t know much about relaxation, I went to talk to some physicists. Both Sven Hartmann, who had just come to Columbia, and Al Redfield, then at IBM Watson Lab in New York City, suggested that I look in the dispersion mode, which should be less sensitive to saturation.¹ The marginal oscillator could only detect in absorption, so I took advantage of Bob Shulman’s generous offer to use his wideline rig at Bell Labs. Despite all this help, by 1962 I had not obtained ‘textbook’ spectra, and, being somewhat naïve and unwilling to make something of the spectra I did have, gave up the project. Ben, who was very patient with

me, rescued me in 1963 when he came back from a meeting with the exciting news that Saupe and Englert had observed high-resolution spectra of benzene oriented in a liquid crystal solvent.² We were able to measure order parameters and ^1H and ^{19}F shift anisotropies in several symmetrical small molecules.³ In 1965, I first heard about cyclobutadiene (C_4H_4), a ‘square’ of C–H bonds and one of the ‘holy grails’ of reactive chemical intermediates. Roland Pettit at Texas had just succeeded in synthesizing the first stable complex of this fascinating molecule,⁴ and he kindly gave us some of the material. We were able to get a spectrum of the oriented iron tricarbonyl complex and determine that, on average, the protons were in a square configuration.⁵ Since that time, a theme for much of my research has been the development of methods for studying the structure of reactive intermediates by NMR.

UNION CARBIDE AND ‘TICKLING’ EXPERIMENTS (1966–67)

In 1966, I went to work for Union Carbide at the Research Institute in Tarrytown, NY, where I had the good fortune to work for Earl Whipple, a whiz at analytical high-resolution NMR, who had the idea of using the spin ‘tickling’ method⁶ to measure the ^{13}C chemical shift anisotropy in methyl iodide.⁷ Earl also suggested looking at the proton NMR spectrum of the fluxional molecule, bullvalene, oriented in a liquid crystal solvent.⁸ The bullvalene experiment gave me my first taste for the intimate relationship between structure and dynamics that pervades much of physical organic chemistry.

IBM YORKTOWN (1967): TRYING NMR OF REACTIVE INTERMEDIATES—BOOM!!

I was discouraged by the ambivalent attitude toward research at Carbide, so in 1967, I went to work at the IBM T.J. Watson Research Center in Yorktown Heights, NY. The job situation at this time was such that one could move without even changing residence! IBM had bought a Varian HA-60-IL, a workhorse machine that I used to start some methods development, a part of my work which I enjoy to this day. During this time, I was exposed to a lot of photo- and reactive intermediate chemistry by my colleagues at IBM; this motivated me to think more about applying the diagnostic power of NMR to metastable intermediates. The opportunity came when Stephan Boué, a postdoc doing photochemistry, came into my office one day and said he had an idea of how to make tetrahedrane.

Tetrahedrane (another C_4H_4 species) is a tetrahedron of C–H bonds and is a highly strained reactive species of great theoretical interest that has yet to be isolated. I rigged up the HA-60 to do measurements at $-150\text{ }^\circ\text{C}$ using propane as a solvent. This was very exciting until we blew up Heinrich Hunziker’s homebuilt quartz lamp (he was my boss!), poking out every corner of his vacuum line during the low-temperature photolysis of the vinylacetylene precursor—more about that later. During this time, I was introduced to the synergism between chemical reactions and magnetic resonance

by Joachim Bargon, who joined IBM in 1969, shortly after his discovery of the CIDNP phenomenon.⁹

DOUBLE RESONANCE IN THE ROTATING FRAME (1970): THE BLEICH/REDFIELD SCHEME

While trying some liquid crystal work on one of the first FT machines then being built at the IBM Watson Laboratory in New York City by Al Redfield and Raj Gupta,¹⁰ I met Al's student, Herman Bleich, who was working on a technique to do high-resolution NMR of rare spins in solids using indirect detection via the abundant spins.¹¹ Although I understood little of the spin dynamics underlying the Bleich–Redfield experiment, I did feel that a sensitive, high-resolution solid state NMR technique like this was necessary for doing matrix isolation NMR and continued working on it. Since Bleich was finishing his Ph.D. and wanted to go into the bio area, as did Redfield, I inherited their apparatus and eventually took it to San Jose.

HIGH-RESOLUTION NMR OF RARE SPINS IN SOLIDS (1971): THE FIRST ¹³C RESULTS

With Bleich's tutoring, and much reading of spin-dynamics papers, I was able to obtain the first high-resolution ¹³C spectrum of an organic molecule in the solid state, and to measure the chemical shift anisotropy for benzene at 233 K.¹² Shortly after this, the MIT group—Alex Pines, Mike Gibby, and John Waugh—published their elegant cross polarization method, which uses direct detection of the rare-spin FID coupled with time averaging, a mode of operation that is simpler and more familiar to chemists.¹³ I could achieve only limited success with the ingenious method that Redfield and Bleich had devised, even though the sensitivity may well be greater than the CP technique for rare spins with a low gyromagnetic ratio or for extremely dilute spins.¹⁴ It was at this time that I got to know the rest of the MIT group, including Michael Mehring and Bob Griffin. I especially enjoyed long walks with Won-Kyu Rhim, who tutored me in the subtleties of spin dynamics. I also met Dave VanderHart, who is one of the 'lone rangers' of solid state NMR and who, with his probing questions, has always forced me to think deeply about spin physics. All have been close friends as well as professional colleagues for many years.

IBM SAN JOSE (1971)

I was transferred by IBM to San Jose in 1971, and within a few months Ray Kendrick, a talented and creative research associate, started to work with me and has remained a friend and indispensable contributor to our research for the last 24 years. Ray has continually generated novel ideas for NMR experiments drawn from his experience as a radio amateur and television transmitter engineer. In 1974, Wiebren Veeman spent the first part of a year stay hunting down sources of noise in the apparatus (including a probe with *plastic* sides) that I was using (against Ray's advice) for the

Bleich–Redfield experiment. Subsequently, Wiebren designed and did experiments demonstrating a nifty high-field ³⁵Cl–¹H cross polarization technique.¹⁵ In addition to being highly innovative, he showed me that the effect of external fields on the motion of nuclear spins can be calculated as well as measured.

MODULATION-INDUCED DIPOLAR LINE NARROWING (1975)

In 1975, Hans-Martin Vieth spent a year at IBM and showed us how to do our first FT experiments and to signal average using a relatively primitive set-up: a transient digitizer, a computer of average transients ('CAT'), and a spectrum analyzer. We also achieved considerable narrowing of dipolar lines in a rotating frame experiment that used strong modulation fields and Hans-Martin did tour-de-force calculations which explained the rather complex spin dynamics.¹⁶ He has a very strong background in the fundamentals of quantum mechanics and measurement theory, and keeps me honest when I periodically try to violate the laws of physics.

VARIABLE TEMPERATURE MAGIC ANGLE SPINNING (1977)

In 1977, Colin Fyfe visited IBM on a sabbatical and got me and my colleague Jim Lyerla excited about doing low-temperature applications of the famous CPMAS experiment done by Ed Stejskal and Jake Schaefer.¹⁷ The motivation was to obtain low-temperature high-resolution spectra of molecules that undergo exchange processes too rapid to study at the higher temperatures accessible with solution NMR. In collaboration with Horst Mossbruger, a premier IBM model maker, Colin designed and built a magic angle spinner that worked at low temperatures.¹⁸ This led to many late nights, fraught with frustration at trying 'get the rotor going', but also led to many exciting results.¹⁹ Since he has a strong background in solid state chemistry, Colin showed me the connections between NMR and other methods for characterizing solids, e.g. diffraction, and made the importance of doing applications very clear. In 1983, Hans Limbach visited for a year and initiated a very successful program in hydrogen-bond dynamics using variable temperature ¹⁵N MAS spectroscopy,²⁰ all the while schooling me in the subtleties of dynamic NMR spectroscopy. We had also developed a method for loading and studying frozen liquids using CP MAS spectroscopy, and my colleague Bob Miller and Volker Macho, from Berlin, discovered that the (formal) degeneracy of the Cope rearrangement in semibullvalene is lifted by lattice effects.²¹

FINALLY, MATRIX ISOLATION NMR (1980): ¹³C SPECTRA OF REACTIVE CARBONIUM IONS IN THE SOLID STATE AND RESOLUTION OF THE NORBORNYL CATION CONTROVERSY

In 1979, I contacted Phil Myhre, a talented physical organic chemist teaching at Harvey Mudd College, who became

interested in my hope motivated by discussions with Colin, to use low-temperature CP MAS to study the structure of carbonium ions. These are molecular ions which are not only thermally unstable, but also rearrange rapidly (on the NMR timescale) so that ^{13}C studies at all but the lowest temperatures yield spectra with average chemical shifts from carbons that occupy more than one molecular site during a measurement. Therefore, in order to obtain unambiguous chemical shift, i.e. structural, data, it is crucial to 'freeze out' these rearrangements by doing experiments at sufficiently low temperatures, often too low for solution NMR work. During a summer visit of only ten weeks, with the help of Carl Rein, a talented model maker, and Alex Kalbin, our glassblower, Phil designed and built a 'poor-man's' molecular beam apparatus²¹ to synthesize and load into a magic angle rotor reactive carbocations that would never see a temperature above 100 K.²² In short order, he started to define the key problems we worked on, and any 'chemical' respectability in our research is due to Phil. We were able to obtain well-resolved ^{13}C spectra and concomitant structural information for the *s*-butyl cation, one of the most elusive carbonium ions.²² Again, with the help of Volker Macho, we were able to obtain spectra of the norbornyl cation at 5 K²³ using a probe designed and built by Ray Kendrick for triple resonance (decouple both ^1H and ^{19}F while observing ^{13}C). It is generally acknowledged that this result gives a very direct solution to the 30 year controversy over the structure of the norbornyl cation.²⁴ The protocol that was developed for low-temperature MAS of carbonium ions also proved useful in obtaining the low-temperature ^{13}C CP MAS spectrum of methylketene, a reactive molecule produced by low-temperature photolysis of diazopropanone.²⁵ This experiment, done by Peter Reisenauer showed that it is indeed possible to do matrix isolation NMR spectroscopy of photolytically generated reactive species. Peter also explained that the explosion we had during our abortive tetrahydrene 'synthesis' was the result of a radical chain reaction; he knew this because the same thing had happened in his lab.

ACCURATE MEASUREMENT OF BOND LENGTHS BY NMR (1981): NUTATION NMR SPECTROSCOPY

After reading Redfield's famous paper on spin temperature in the rotating frame and rotary saturation,¹ I understood that a strong resonant field would selectively eliminate chemical shift effects while preserving dipolar coupling, which is inversely proportional to the third power of the internuclear distance. Therefore, I thought it might be possible to use this method to determine the geometry of reactive intermediates by accurately measuring bond lengths. Such an approach would be more general than diffraction techniques since reactive species are usually generated and isolated in a highly disordered matrix. Although I had initial success using rotary saturation,¹ a CW rotating frame experiment, Veeman suggested²⁶ that it might be possible to use transient nutations.²⁷ Since I felt that it was important to have a 'simple' method, I decided to use a train of single-phase rf pulses to produce a transient nutation. Fourier transform of the nutation signal would yield a 'nutation NMR' spectrum consisting of a Pake doublet²⁸ which would then yield the desired dipolar splitting and

corresponding bond length. Although an approach like this is conceptually simple since there are no phase shifts, the instrumental price is high and was paid largely through the efforts of Don Horne, a physicist at IBM who does beyond-state-of-the-art electronics and continues to be the final word for us on our most challenging electronics projects. In 1981 we made our first successful measurement of a carbon-carbon bond length²⁹ and eventually increased the accuracy of the measurement to 1%.³⁰ At that time, much research was being done at IBM San Jose on organic conductors. Polyacetylene was one of the most interesting of these since it had been predicted that the ground state of the all-*trans* isomer involved soliton excitations.³¹ The notion of alternating bond lengths was a consequence of this hypothesis and it seemed like a 'natural' to test this idea using nutation NMR. My colleague Tom Clarke made the appropriate doubly- ^{13}C labeled material and we observed two Pake doublets, the first direct proof for bond alternation in *trans*-polyacetylene.³² In collaboration with Tom Katz at Columbia, we used dipolar spectra like this to probe the mechanism by which acetylene is polymerized.³³ Our goal for developing nutation NMR to measure reactive-molecule geometry was also reached with a measurement of the carbon-carbon bond lengths in the *t*-butyl cation.³⁴ So, solid state NMR methods had been used to solve key problems in fields as disparate as solid state physics and physical organic chemistry. In 1988, Mario Engelsberg, a Brazilian physicist with a very strong resonance background, spent a sabbatical and calculated and confirmed experimentally that scaling of the dipolar splitting in a Carr-Purcell sequence depends linearly on the rf duty factor.³⁵ This result made it possible to distinguish between bonds that are much closer in length than is possible by nutation NMR since the latter scales dipolar splittings by one-half while scaling in the Carr-Purcell sequence can be minimized by reducing the rf duty factor. Shortly thereafter, this result proved to be critical since it enabled us to make the first measurement of the molecular geometry of C_{60} .³⁶

DYNAMIC NUCLEAR POLARIZATION (1984)

In 1979, I met Robert Wind, then at Delft, who spent two summers in my laboratory, during which he came up with a number of highly innovative ideas, one of which was to apply modulation-induced line narrowing¹⁶ to do one of the first solids imaging experiments.³⁷ He also had the idea of a nuclear solid effect which we demonstrated during one of his stays.³⁸ I was motivated by Robert's success with DNP to use it selectively to obtain NMR spectra of molecules at the surface of metal particles. Unfortunately, DNP did not fare well in my hands; however, in the process of setting up a program, I had the opportunity to interact with a number of first-rate electron spin resonators like David Singel and Günter Maresch. David designed our DNP probe/spectrometer³⁹ and suggested measuring the chemical shift in a conductor by suppressing the Knight shift via saturation of the ESR, an experiment done for ^{13}C in an organic conductor by Waldemar Stöcklein, a postdoc from Bayreuth.⁴⁰ A similar experiment was done independently by Robert Wind, in collaboration with Michael Mehring.⁴¹ Günter not only developed our low-temperature

DNP capability but also did experiments on interfaces⁴² and DNP spin dynamics.⁴³

MAGIC ANGLE SPINNING AT LIQUID HELIUM TEMPERATURES (1986)

In 1986, Harald Seidel, who came from Stuttgart with a strong background in ESR and microwave instrumentation, and Walt Baier, a highly-skilled model maker, were designing and building a low-temperature DNP–MAS probe. In order to minimize interference with the microwaves, I had decided to use a spinner design⁴⁴ in which only the glass tube and sample would be in the coil/cavity region. While bench-testing the low-temperature spinning for this probe, we noticed that it should be possible to lower the sample temperature without limit since, unlike a probe we had previously used (with difficulty) for spinning at temperatures below 77 K,⁴⁵ the cooling and spinning gas functions were separated. This idea had already been used by Kurt Zilm at temperatures close to 77 K.⁴⁶ However, since we were interested in magic angle spinning at temperatures considerably below 77 K, it was necessary to use helium as a spinning/bearing gas. It is well known that high-power decoupling in a helium atmosphere causes gas discharge, preventing detection of the NMR signal.⁴⁷ We solved this ubiquitous age-old problem by using a remotely tuned probe designed by Ray Kendrick, and careful construction practice.⁴⁸ Our low-temperature MAS probe has worked well at temperatures down to 5 K⁴⁸ and has been used to determine the elusive structure of some carbonium ions.⁴⁹

COHERENT RAMAN BEATS IN MAGNETIC RESONANCE (1986)

While collaborating with my colleagues Bob Shelby and Roger Macfarlane to do rf–optical double resonance experiments,⁵⁰ I became aware that Dick Brewer at our lab had observed some optical coherence phenomena that he and Erwin Hahn had analyzed and called coherent Raman beats.⁵¹ It seemed that it might be possible to borrow this idea from optics and in 1985, in collaboration with Po Wang, then at IBM, I used coherent Raman beat detection to do a multiple quantum NMR experiment in which the evolution, mixing, and detection periods were combined, with potentially large savings in time.⁵² I was also trying to use the same approach to detect electron spin echo envelope modulation (ESEEM),⁵³ but was not successful until I teamed up with Mike Bowman, then at Argonne National Laboratory, who carried out some beautiful experiments.⁵⁴ He and Mel Klein have since refined this method to the degree that it seems to hold promise as a sensitive method for detecting highly resolved nuclear sublevel coherences in paramagnetic systems.⁵⁵

BUCKMINSTERFULLERENE (1990): A DREAM FOR NMR SPECTROSCOPISTS

An all-carbon molecule that is ‘round’ captured the imagination of the scientific (and even layman’s) world so that in

1990, when Don Bethune at our lab started a program to study C₆₀, I was intrigued by the possibility of using solid state NMR to probe the dynamics of C₆₀, which I thought would be very ‘slippery’ in the solid state. As a result of that interest, and an exciting collaboration over a period of only a little more than a year, Don, Bob Johnson, Jesse Salem, Mattanjah deVries, and I did the first solid state magnetic resonance experiments on fullerenes and metallofullerenes,⁵⁶ including freezing out the reorientation of C₆₀.⁵⁷ We also made the first measurement of C₆₀ geometry using the resolving power of the Carr–Purcell method to observe two Pake doublets from bonds of nearly equal (1.40 Å and 1.45 Å) length.³⁶ Patrick Bernier, from CNRS in Montpellier, who visited IBM in late 1990, collaborated on the C₆₀ bond-length measurements,³⁶ while Harry Dorn from Virginia Polytechnic Institute was also bitten by the fullerene ‘bug’ during a sabbatical stay in 1991, and broke significant ground in fullerene separation technology.⁵⁸ Both have since developed strong programs in fullerene research.

NEW GROWTH ON THE EVERGREEN (1991): FORCE DETECTION OF MAGNETIC RESONANCE—WILL IT BE POSSIBLE TO DETECT ONE SPIN AT A TIME?

The field of magnetic resonance continues to bring me the excitement of good science and the personal satisfaction of meeting and working with new colleagues. In late 1991, my colleague Dan Rugar, a premier force microscopist, told me that John Sidles, who is a medical physicist from the University of Washington, had the idea of detecting magnetic resonance using force, with the incredible potential for *imaging a single nuclear spin*!!⁵⁹ Although I got very excited, I was too involved in fullerene work to be of much help, but did suggest doing ESR, so Dan went off and did the first force detection of magnetic resonance.⁶⁰ We have recently collaborated on an experiment that demonstrates the remarkable potential of force detection of NMR, observing 1.6×10^{13} spins in a single shot at room temperature in a field of 2.4 T.⁶¹ This result, which corroborated Dan’s theoretical expectations for the performance of the microscope, has encouraged us to continue a program to develop a magnetic resonance force microscope capable of imaging one nucleus at a time. A workable method with this capability could become an extraordinarily powerful tool for the determination of molecular structure.

EPILOGUE

I hope it is clear that many of the ideas for experiments that I have done have come from co-workers with backgrounds ranging from synthetic and physical organic chemistry to solid state physics. As a result, part of the magic of NMR for me is that it encompasses such a broad range of disciplines. As one who has said (if I don’t admit it, many colleagues will remind me) on many occasions that ‘NMR is dead’, I now have also to admit that I marvel at this perennial of science and am optimistic that there will continue to be lots of ‘boomlets’ and perhaps a few more big ‘booms’ in new ideas and activity in the years to come.

Biographical Sketch

Costantino S. Yannoni. b 1935. B.A., 1957, Harvard College, M.A., 1960, Ph.D., 1966, Chemistry, Columbia University, USA. Staff member, Union Carbide Research Institute, Tarrytown, NY; research staff member, IBM Research Division, T.J. Watson Research Center, Yorktown Heights, NY 1967–71; Almaden Research Center, San Jose, CA, 1971–present. Approx. 100 publications. Research specialties/interests: development and application of solid state NMR methods for solving problems involving structure and dynamics in materials, especially organic reactive intermediates; magnetic resonance analogs of coherent optical phenomena; current interest is force detection of magnetic resonance for ultra high-resolution imaging.

Young, Ian R.: EMI's Venture into NMR—An Industrial Saga

Ian R. Young

Hammersmith Hospital, London, UK

EMI began work on magnetic resonance imaging in 1974, simply because the company wanted to be involved in any, and all, modalities with any potential to rival its then burgeoning CT X-ray business. It sought scientists to work on magnetic resonance imaging from amongst its employees on the basis that if someone had some experience in magnetics of any kind, he (or she) must know sufficient about nuclear magnetic resonance. Thus Hugh Clow and W. S. Percival, who were those first involved, had extensive backgrounds in magnetic tape research. Peter Walters was recruited to do the necessary computer simulations while I was originally employed to develop methods of handling and using a unique magnetic tape on which a permanent coding had been impressed which could be detected by special means, but which was transparent to other, conventional, recording and reading. I soon discovered that that project was much less significant in EMI's eyes than the development of new magnetic deflection systems for scanning X-ray systems, and the development of nuclear magnetic resonance imaging (as it then was—according to folklore, the 'nuclear' was dropped in 1983, after an emotional misinterpretation at the site of a new scanner complex in Cleveland, OH).

The original EMI plan was to build a scanner based on a 0.1 T resistive magnet (the prototype of which was bought from Walker Magnetics, Danbury, CT) with a single driven equilibrium Fourier transform (DEFT) method of data acquisition. The gradients were planned to be outside the magnet structure, driven by thyristor-switched resonant discharge circuits, and image formation would be by back projection (entirely predictably in the light of EMI's CT experience).

All the gradients (including slice selection and during signal acquisition) would be sinusoidal so that, in order to meet the Nyquist criterion and cover k -space uniformly, the data were to be sampled at nonuniform time intervals. (This method was fully investigated, though only published in a pair of patents.)^{1,2}

Colin Harrison, with a background at CERN and in precision power engineering, made extraordinary efforts to make the concept work during 1977, but by the end of that year we had decided to start again, and Colin built a set of more conventional gradient coils and I designed a new electronics unit to operate these. Mike Burl, who had recently joined us, developed the rf system for the machine. We continued to use one of the resonant discharge units for the slice selection (Z axis) coils but X and Y were driven by amplifiers originally intended for driving an electronically swept CT X-ray tube. The slice-selection gradient pulse was sinusoidal (as was the rephasing one) and a sine⁵-shaped rf profile was used for the rf transmitter pulses. This was generated using an analog network, but the amplitudes and shapes

of the scanning gradients were formed digitally, though the logic was all hard wired. The nonlinear sampling circuitry was built the same way with the time intervals between the nonlinearly spaced sampling pulses blown into programmable read-only memories (PROMs) by hand. The values used were obtained by sampling the signal from a small phantom linearly, averaging multiple FIDs until we had reduced the signal uncertainty to manageable proportions, then calculating (using a pocket calculator) the varying time increments needed to meet the Nyquist criterion, and achieve constant phase increments.

The machine's computer was a small 16-bit Data General Eclipse, similar to that being used on the company's CT scanners, with the back-projection algorithm loaded into the writeable control store (the feature which had led EMI to choose the computer in the first place). Essentially we could, initially, acquire a 90° – τ – 90° image with a back-projection scan incremented in 1° steps, and reconstruct and display the data as a 128×128 image interpolated to a 256×256 matrix, using a 10 mm slice. Image acquisition took 3 min (with one average, or 6 min with two, which was the extent of the options we originally had).

We began to acquire phantom images with some degree of respectability in late 1977 early 1978, but an attempt to image a volunteer head was quite disastrous, resulting in something like a frayed rabbit with drooping ears. The attempt produced a crisis in that Peter Walters felt we had violated the machine's virginity in the process—because Colin, Mike, and I had got fed up with waiting for him and Hugh Clow to appear and made the attempt ourselves.

We decided we simply had not got adequate stability and accuracy in the electronics, and homogeneity in the magnet and tore the machine apart, replacing the magnet adjustments supplied by the manufacturers with our own, and giving up the YIG EPR probes which we had been using for field monitoring in favor of homebuilt NMR ones.

The failure was multiply embarrassing in that the company, coming under severe pressure in its CT business and anxious to share the financial risk of this new development, wanted to collaborate with the Department of Health and Social Security (DHSS) as it had done with the original CT scanner. It also knew that the vast British GEC Company (which had recently employed Waldo Hinshaw who had shortly before left Nottingham) was preparing a rival proposal.

Our initial interaction with DHSS, represented by John Williams, was not encouraging. John was very familiar with Peter Mansfield's work and his recent publication of the first description of echo planar imaging (EPI).³ We knew of Peter's paper, and had Raymond Andrew and Bill Moore as consultants, but could not reconcile what we knew of the method, and its claimed performance, with our own theoretical and practical results. Colin, Mike, and I concluded we would have to go to a higher operating field, and the proposal which was finally submitted to DHSS involved a field cycling resistive whole body magnet, normally operating at 0.1 T, but switched to 0.3 T to image.

In retrospect the concept was insane, certainly at that time and with the specification we wrote for it. Nevertheless, after a presentation to the DHSS scientific branch (headed at the time, as during the original CT work, by Gordon Higson, a man with a quite extraordinary record for backing winners, and a genius for very clear assessment of both failure and success,

as he later described),⁴ it was agreed that EMI and DHSS would jointly develop a prototype NMR imaging machine to be installed in a hospital in London to be selected in the next few months. The program would begin on 1 July, 1978.

After the event, in July, Colin and I spent long hours contemplating the horror of what we had done, faced with the need actually to design and build this new magnet system (bearing in mind that we were still struggling to get our first vaguely adequate image of a human head—something we did not actually achieve until early September, and which was published in *New Scientist* shortly after,⁵ see Figure 1). Quite fortuitously there was a cryogenics conference, with an associated trade exhibition, in London in August, and Colin went to that to see if any manufacturer would even talk to us about a whole body magnet. He came back with the names of Oxford Instruments and Thor Cryogenics and we gave both of them our magnet specification and asked for quotations.

Both responded, Thor with what I considered was the better specification but with an insistence on a refrigerator system. We were dubious both about the reliability of this item and the substantially increased cost of the Thor magnet. The latter was enough to ensure that Bill Ingham (the then Director of EMI Central Research Laboratories) made it plain that it would be preferable if we were to choose Oxford, and a contract was signed to a value of £70 600 for the design and purchase of a magnet to operate at 0.3 T with a clear bore of 1050 mm to be delivered to EMI CRL at Hayes, Middlesex,

Figure 1 First vaguely successful NMR image of the human head taken in September 1978 using a Walker 0.1 T resistive magnet. The method was filtered back projection, using a half-Fourier data acquisition (including non-linear sampling) with 180 angular increments of 2° each. Slice thickness was 10 mm. Repetition time was 1 s, and the time between selective rf pulse centre and the start of data acquisition was 5 ms

in late 1979. A proportion (£10 000) of the cost was to pay for the design. (Though EMI never did anything about the matter, it could be argued that EMI actually owned the design of the Oxford whole body magnet!) Ingham (who had spent most of his working career in EMI military electronics) insisted that Oxford sign endless confidentiality agreements. As Raymond Andrew pointed out to us, these held for about three weeks before Oxford set out to see who else might be interested—long enough to print descriptive leaflets and make some contacts.

We chose the Data General Eclipse 250 computer—a 16-bit top of the range unit that was manufactured for about six months before being superseded by the 32-bit VX4000 series. This was a mistake in retrospect, but a worse one was our inability to obtain approval to buy an array processor. EMI CRL were more than happy that we should use the one they were developing for a new CT scanner. We saw that as largely underdeveloped and underfunded. It looked to us that the CRL management saw our role as funding the software needed for this array processor. We wanted to buy the Data General product compatible with our computer—and in the end nothing was fitted.

In the spring of 1979 sadly, Colin Harrison left us (going to work for IBM in San Jose) and Alasdair Hall joined us as his replacement. Alasdair thereafter carried the load of developing the facilities and techniques needed to cope with the new cryomagnet.

In planning the new machine, we decided we had to achieve real flexibility of technique, and that the hard-wired approach of the resistive prototype was impracticable. In fact, after a steady improvement in head image quality in the early months of 1979, using volunteers since neither animals nor patients were really feasible in the laboratory environment, we did not seem to be making significant further progress. We began to redevelop the prototype to give it some measure of sequence variety.

During this time we were seeking a suitable hospital site. My first choice was the hospital at which the original CT head scanner had been placed. In spite of the assistance of my immediate boss Alan Blay, Dr. James Ambrose, the neuroradiologist at that hospital, declined the offer saying that either the machine would fail, in which case he would waste two years of his time, or it would succeed in which case he would be flooded out with visitors, as he had been with the CT scanner (of which he had had the first clinical unit), and that would waste his time also.

We next offered the machine to the Hammersmith (partly because my brother had done his Ph.D. there), and Professor Robert Steiner agreed to install the machine in a building to be funded by the DHSS with some support from the University of London, since the new facility would provide better accommodation for the Medical School Department of Anaesthetics. Professor Steiner asked Professor Frank Doyle to be the direct link with, and supervisor of, the new project. In the fall of 1979, he and Jackie Pennock began to bring rabbits out to Hayes in circumstances of great secrecy, and started a series of experiments which included the use of paramagnetic contrast agents.

EMI, in the meanwhile, was under severe financial pressure because of the heavy losses both in its medical and music businesses. In the fall of 1979, another large electrical company, mainly involved in domestic electrical and electronic

Figure 2 Very early (late 1979) inversion recovery images of the brain of a volunteer, showing the dramatic contrast between gray and white matter that would become the method's hallmark. (Acquired as described for Figure 1, except that the 360 angular increments had a 1° interval, and there was an inverting, nonselective, 180° pulse 300 ms ahead of the 90° one)

equipment and lighting, made an offer to take the company over. On the day the new management was installed we finally achieved the beginnings of satisfactory high contrast inversion recovery images (Figure 2), and within the next three weeks spin echo images, including a pulsed gradient spin echo experiment to measure flow (based on the Stejskal and Tanner diffusion experiment⁶ and using the same process that we published finally in 1984).⁷ The latter two experiments produced results, but with the sequence parameters we had chosen, retrospective wisdom reveals they were not destined to be exciting from a contrast point of view. We were simply lucky in that we reworked the spin echo two years later with patients, and were able to publish the huge efficacy of spin echo sequences in time to avoid someone else getting there first.⁸

Bill Ingham's concern about security, which ultimately led to the cryomagnet being installed in a room at CRL in which the windows had been painted out, extended to publications. The one exception was patenting—which he encouraged feverishly. On Friday nights we used to retire to a pub and draw up ideas to patent next week, always attributing part of the invention to the brewer. The idea was to get this past the management, since one of our party was our patent engineer who could always delete the reference at the last moment. One irony was that the patent department recommended we did not apply for a patent on the flow encoding technique, as the prior art was too substantial. Hindsight shows this was too pessimistic a view!

During late 1979 and 1980, collaborating with a general practitioner from Portsmouth and a neurologist from Hammersmith, we worked-up the old resistive machine, including one day when we scanned 10 volunteers in 8 h, and recommended to DHSS and EMI (by then Thorn-EMI) that, regardless of the success of the cryo machine, we should launch a product based on the 0.1 T resistive magnet. The new management, who were much more concerned to get out of the medical business altogether, were uninterested.

The cryomagnet was delivered in early May 1980, with the field initially set at 0.26 T, and the system assembled by July. Because of a lack of software on the Eclipse 250, we reconstructed data on the computer belonging to the 0.1 T machine.

We had, we considered, good images by October, and began to discuss the transfer of the machine to Hammersmith and the new building. John Williams of DHSS decided that the acceptance test for the machine was that it should produce the same highly contrasted T_1 -weighted inversion recovery images that we were getting off the 0.1 T machine. I decided I was going to warm the magnet up over Christmas 1980, and ship it on 4 January, 1981. We simply could not get matching images (because we did not understand the field dependencies of tissue relaxation behavior—there were so few relevant results around) and, in the end, with the magnet running out of helium, we cut the field to 0.1 T on 22 December, caused a partial quench in the process with subsequent accelerated boil-off, and finally got an acceptable image on 23 December, just before the magnet finally quenched.

The magnet was shipped as planned and installed at Hammersmith very quickly. We then found a major problem. For reasons which again look bizarre in hindsight, we had used huge valve amplifiers to run the X and Y gradients, with rail voltages of 6 kV and demineralized water cooling. The atmosphere at Hammersmith was more humid than at Hayes and we suffered continuous corona from the gradient windings. In the end we had to strip the system down and reinsulate the gradients in situ. This meant that we were not able to begin scanning until March, and the machine sat there forlornly with its rf screen raised, looking for all the world what the hospital called it—'a white elephant'. Professor Steiner and his colleagues spent some time trying to decide what to do with the space when the machine was removed (something that was expected imminently).

Professor Steiner had recruited Graeme Bydder as the radiologist responsible for supervising the machine and its research in mid-1980. Though Graeme attended one or two meetings prior to that, he did not join until January 1981. When the machine was finally ready to begin operation we decided that we needed to understand the behavior of tissue signals as we changed field. We felt we knew about 0.1 T and that we should increase to our real operating field in 0.05 T steps. We set the field at 0.15 T and began volunteer studies. Then, in March, Graeme began to put patients through the machine and, thereafter, no further changes were permitted (even if Mike Burl and I did do experiments on odd days thereafter at higher fields). Post-September 1981 the field did not change again, and so this machine was probably the only one in NMR history of which the field was reduced.

The first (*Lancet*) papers^{9,10} were prepared in June and July, very sadly in the absence of Frank Doyle who had suffered a severe stroke in May. True to his beliefs, Bill Ingham found it desperately difficult to agree to their publication. He made the mistake of going on vacation, though phoning from any public callbox he passed in the remotest part of the Scottish Highlands, to raise further objections to the papers' submission. Graeme and Robert sent them off anyway.

In their efforts to get out of medical equipment, Thorn-EMI wanted to do a deal with General Electric (GE), and a party from GE, which included Bill Edelstein, visited CRL in early fall 1980. Technicare (including Waldo Hinshaw by

Figure 3 First cryogenic magnet shown installed in its site at Hammersmith Hospital, with its trunk raised in characteristic pose. There were many who thought at the time that the photograph was taken that its continued presence was more likely to be measured in weeks than years

then) also came and, I believe, Philips also wanted to acquire the NMR work. Thorn-EMI were, I think, only interested in the GE proposal, and a contract was drawn up between the two companies which was due to be finalized on 31 January, 1981. The contract required a third signature however (that of the DHSS, as part-owner of the project), but the British GEC, using all its influence, succeeded in preventing this being appended, and the deal collapsed. GEC (in April) acquired Picker, but it was not until the end of the following September that they actually bought the Hammersmith project from Thorn-EMI, leaving us in a curious limbo for eight months. We found out what it was like to be unwanted! GEC had to wrestle with the fact that, by then, they had their own program, which was being heavily influenced by Bill Moore and Neil Holland who were using the SSFP ideas they had pioneered with Waldo Hinshaw, whilst we had turned against steady-state methods. It was not an easy situation and I think it is fair to say that this dual parentage of ideas was a problem that Picker subsequently found very troublesome to resolve.

The sale of Thorn-EMI to GEC was completed just before the Winston-Salem Conference in September/October 1981 at which magnetic resonance imaging came of age. The machine (which is shown in Figure 3 in its favorite 'white elephant' pose) survived, and will ultimately wend its way to the Science Museum in London. Sadly, largely because the magnet gaskets are leaking, it was taken out of service in mid-1993. On the whole it did not have a bad run.

1 INTRODUCTION

Whole body MR imaging (MRI) at the commonly used field strengths makes demands on rf coil design that cannot be met by a conventional multiple-turn solenoid nor by a microwave cavity. The dimensions of the sample volume are neither a small nor a large fraction of a wavelength at the Larmor frequency. Whole body MRI employs a new rf coil technology which combines lumped and distributed elements. Such a structure is better characterized by the term 'resonator'. The term 'coil' implies a lumped-element multiple-turn solenoid tuned by a discrete capacitor, with a clear spatial separation between the inductor that stores energy in its magnetic field and the capacitor that stores energy in its electric field. On the other hand, a cavity stores both electric and magnetic energy somewhat diffusely; each extends over a significant fraction of the enclosed volume. The MRI whole body resonator creates a homogeneous B_1 field within the patient by distributing the current over a large portion of its surface area, as in the case of the cavity resonator. By confining most of the electric field energy to multiple, discrete capacitors distributed over a large portion of the surface area, the MRI body resonator minimizes the electric fields within the patient and reduces dielectric losses.

Most whole body MR scanners use a large-bore superconducting solenoidal magnet to supply B_0 . The rf resonator must produce a homogeneous, transverse rf field and provide unimpeded axial access for the patient to the center of the magnet. To generate a rapidly oscillating B_1 of about 2.5×10^{-5} T in an area of about 1 m^2 , the resonator must sustain voltages on the order of 10 kV.

The birdcage resonators¹ in Figure 1 were developed to accommodate whole body MRI. The basic birdcage resonator includes two circular conductive loops, referred to as endrings, connected by a number of conductive straight segments, evenly spaced on the surface of the cylinder. The conductive framework constitutes the inductive element of the resonator. A multitude of capacitors inserted along the conductive paths provide distributed storage of electric field energy. The novel feature of a birdcage resonator is that one of its natural resonant modes produces a homogeneous, transverse rf magnetic field within its volume. Furthermore, the ideal current distribution can be achieved by using the same value of capacitor in all the capacitor locations.

This article treats the design and construction of volume resonators with particular focus on the birdcage resonator. The

Figure 1 (a) Lowpass birdcage resonator with multiple capacitors on each straight segment. (b) Highpass birdcage resonator with polar coordinates

first section covers general principles applicable to large resonators. The next section discusses the birdcage resonator extensively to give an intuitive understanding of how an ideal birdcage works. In spite of the seemingly straightforward structure shown in Figure 1, an actual birdcage embodies numerous imperfections which can alter the operation of the birdcage. Without a full understanding of all the issues, attempts to rectify one problem may create new difficulties. Sections on design and construction aid a researcher to build a birdcage suitable for a particular research project. The final section reviews alternative treatments of the birdcage and other volume coils or resonators.

2 GENERAL PRINCIPLES FOR LARGE-VOLUME RESONATORS

It is assumed that the reader is familiar with the basic concepts of conventional rf coil design such as the coil sensitivity factor B_1/I , the coil quality factor Q , coil losses and tissue losses, the coil filling factor, quadrature excitation and reception, tuning and matching, etc. (see *Sensitivity of Whole Body MRI Experiments; Radiofrequency Systems and Coils for MRI and MRS*). Some of these topics are also covered by Hayes et al.²

The body coil primarily excites the spins with a homogeneous B_1 . Field homogeneity is particularly important for pulse sequences employing multiple spin echoes, where errors in flip angle compound. The body coil can also be used for signal reception, but this function is often better satisfied by surface coils or phased arrays specialized for specific body parts. (see *Surface and Other Local Coils for In Vivo Studies; Whole Body Machines: NMR Phased Array Coil Systems*). Whole body MRI exposes a large volume of tissue to the high-frequency magnetic field. Eddy currents induced by the rf field usually become the dominant power loss mechanism compared with coil losses. When this condition occurs, increasing the filling factor or reducing coil losses will produce only marginal improvements in the signal-to-noise ratio. In traditional NMR

with small sample losses, a solenoid wound on a cylindrical sample is inherently more sensitive than a structure that produces transverse rf fields in the cylinder. The long solenoid has a better filling factor because much of its magnetic energy is channeled through the sample volume by the conductive cylindrical walls. The transverse field stores more magnetic energy outside the sample because the flux must exit through the cylindrical walls. When sample losses dominate, the differences in filling factors for the two configurations no longer matter.

The use of a high-field superconducting solenoidal magnet imposes constraints on the design of the whole body rf resonator. Axial access for the patient requires the resonator to have open ends, which are a major source of rf field inhomogeneity. Rf field homogeneity can be improved by lengthening the resonator, but this has the disadvantage of increasing the power deposition during excitation and reducing the signal-to-noise ratio during reception. The magnet geometry imparts cylindrical symmetry to the available sample volume and strongly suggests the resonator uses the same symmetry. Such symmetry implies that a circularly polarized rf field is naturally preferred over linear polarization, because there is no preferred x - or y -direction in a superconducting magnet. Circular polarization decreases power deposition during quadrature excitation and increases the signal-to-noise ratio during quadrature reception. This is an added advantage that a transverse resonator has over the solenoid, whose geometry favors a linearly polarized B_1 .

A long solenoid approximates a constant circumferential surface current density that produces a homogeneous field in the axial direction. To produce a homogeneous transverse magnetic field in a long cylinder, the surface current density must be parallel to the long axis and proportional to $\sin\theta$ or $\cos\theta$, where θ is the polar coordinate azimuthal angle measured from the x axis. The $\sin\theta$ current distribution creates a linear polarized field along the x direction. For a particular instant, the positive values of $\sin\theta$ imply current is flowing in the positive z direction on the top half of the cylinder, and the negative values of $\sin\theta$ correspond to current on the bottom half of the cylinder flowing in the negative z direction.

In an rf solenoid, the conducting surface can be opaque to rf fields because the desired field is parallel to the cylindrical surface. For a transverse field resonator, the cylindrical surface must be both conductive and transparent to the emerging rf field. Such a surface can be approximated by a large number of evenly spaced copper wires or foil strips. The field homogeneity is disrupted in the sample volume for a distance comparable to the spacing of the conducting wires. If conductor width is small compared with the spacing, high current densities generate large local field concentrations near the conductors. High current densities also correspond to higher ohmic losses. If the conductors are too wide, the field is concentrated in the narrow slots between the conductors. A 50% coverage by the conductor is an arbitrary but useful compromise between the two extremes.

Because of the large voltages induced by rf fields in the cross-sectional area of the sample volume, only a single-turn inductor or multiple turns connected in parallel are desirable. Extraneous inductance, that is, any magnetic field that does not intersect the sample, should be minimized. For example, the lead inductances of the capacitors are eliminated by placing the

capacitors directly on the conducting surface of the resonator. Likewise, high concentrations of current density also increase inductance because the locally enhanced magnetic field stores excess magnetic energy.

Distributing a large number of capacitors in series around the surface of the resonator has numerous advantages. First, the large voltages are broken up into series of small voltage steps, creating a number of virtual ground planes intersecting the resonator. Hence, voltage on no single component is elevated so far above ground that a coronal discharge occurs. The many small voltage steps create weaker, alternating stray electric fields that average to zero at shorter ranges than would a large dipole electric field from a single capacitor. This reduces the effective stray capacitance of the resonator to ground and thus raises its self-resonant frequency. Dielectric losses occur in the sample when stray electric fields from the coil's capacitors distort the electric fields induced in the sample by the rapidly changing rf magnetic field. The even distribution of capacitors effectively substitutes for a Faraday shield between the sample and the coil. Multiple capacitive breaks in conducting paths of the resonator also reduce eddy currents generated by the switched gradient fields during the imaging process. Many relatively inexpensive, discrete capacitors substitute for the more bulky and expensive vacuum capacitors commonly used in high-voltage rf circuits.

3 FUNDAMENTALS OF BIRDCAGE RESONATORS

3.1 The Basic Lowpass Birdcage

The chief advantage of the birdcage resonator is its ability to approximate the ideal sinusoidally weighted surface current on a cylinder with a large number of discrete conductors. To understand the origin of the sinusoidal distribution, consider the resonant properties of a finite length L of transmission line. If both ends are open circuits, the transmission line supports standing wave resonances for all frequencies for which the length is an integer number of half wavelengths long. If the two ends of the transmission line are joined to form a closed loop, the new boundary condition gives resonances when the length equals an integer number m of full wavelengths, that is, $m\lambda = L$. Now consider a twin-lead transmission line formed from two closed loops of wire around the circumference of the cylindrical sample volume. For the standing wave with one wavelength, the magnetic field between the wires enters the sample volume on one side and exits it on the other side. For an air dielectric between the wires, the desired resonance at $m = 1$ occurs at too high a frequency compared with the Larmor frequency. The capacitance per unit length of the transmission line determines its phase velocity. Lowering the phase velocity lowers the resonant frequency of the line. The transmission line can be made to resonate at the Larmor frequency either by filling the volume surrounding it with a high-dielectric material or by shunting the gap between parallel wires with evenly spaced discrete capacitors. The two wire loops can be separated widely to form the endrings of the birdcage because the capacitance per unit length of the transmission line no longer depends on the spacing of these wires. The current in the capacitor leads approximates the

sinusoidally weighted current density on the surface of the cylinder. That is, the sum of the fields generated by the lead inductances of the discrete capacitors create the homogeneous $\mathbf{B}_1$ field in the enclosed volume. The resulting configuration is a lumped element delay line with N repeat elements, and can support resonant modes for $m = 1, 2, \dots, N/2$ (if N is even).

The resonant current in the straight segments can be proportional to $\sin m\theta$ or $\cos m\theta$, where values of θ are incremented by $2\pi/N$. The discrete wires correspond to a digital sampling of a continuous current distribution. The highest frequency resonance, $m = N/2$, corresponds to the Nyquist condition, where successive straight segments have currents with opposite phase. Each mode except $m = N/2$ is doubly degenerate because there are two current distributions with the same frequency. The cylindrical symmetry of the birdcage implies that $\sin(m\theta + \alpha)$ and $\cos(m\theta + \alpha)$ with an arbitrary α are also equally good choices for the two modes. For the ideal birdcage, there is no preferred azimuthal direction to call the x axis. The homogeneous mode ($m = 1$) occurs at the lowest frequency. The higher-order modes ($m = 2, 3, \dots, N/2$) produce rf magnetic fields that decrease to zero on the central axis of the cylinder. The highest mode has the shortest range of penetration into the central volume of the cylinder. The cut off frequency occurs because the lumped element configuration resembles an N stage lowpass filter. This form of resonator is, therefore, referred to as a lowpass birdcage resonator [Figure 1(a)].

The two degenerate modes, $\sin \theta$ and $\cos \theta$, are orthogonal modes, both in the sense that the two functions are mathematically orthonormal and in the sense that their respective fields are perpendicular to one another. The two modes can be excited simultaneously and independently of one another. Equal simultaneous excitation of both modes with the same phase would create a linearly polarized field in the $\theta = \pi/4$ direction. Equal simultaneous excitation of both modes with a $\pi/2$ phase difference creates the circularly polarized field needed for quadrature excitation.

For simplicity, most of the following discussion will consider the birdcage operating with a linear polarized field along the x direction. It is also instructive to take a global viewpoint toward resonators in terms of how they store energy. Consider the composite lowpass birdcage structure as a resonator which alternately stores energy in electric fields and magnetic fields. All the energy is stored as magnetic field energy in the space in and around the resonator at the instant that all capacitors are completely discharged and the elemental currents are at their maximum values. Likewise, all the energy is converted into electric field energy at the instant when the elemental currents cease flowing and the capacitors are charged to their maximum values.

For the $\sin \theta$ mode, the birdcage resonator can be thought of as a single current loop encircling the x axis but branching and recombining in multiple short parallel paths. The current goes up one side of the cylinder, around the two halves of an endring, down the other side and across the other endring to the starting point. The total current is the sum of all the currents going the same direction on one-half of the cylindrical surface. One half of the endring current enters the endring from straight segments between $\theta = 0$ and $\theta = \pi/2$, has its maximum at the point $\theta = 0$, and then exits the endring into

the straight segments between $\theta = 0$ and $\theta = -\pi/2$. Hence, the endring current is a discrete sum that is approximately proportional to $\cos \theta$, which is the integral of the surface current. The net effective inductance of the birdcage corresponds to all of the magnetic energy storage arising from the total current. As the number of straight segments is increased, the net inductance decreases toward a lower limit. For a fixed field strength at the center of the birdcage, adding straight segments reduces the current required in each segment and decreases the field inhomogeneity in the proximity of each segment. Lowering the fluctuations in field strength near the straight segments reduces the stored magnetic energy density. The lowest inductance corresponds to a homogeneous field with an infinite number of straight segments. Because of their high current density, endrings may be the dominant source of inductance in the resonator.

All of the capacitors on one-half of the cylindrical surface are effectively wired in parallel, but they are not weighted equally because they carry differing amounts of current and hence store different amounts of the electric field energy. The collective net capacitance of one half surface is wired in series with the net capacitance of the other half surface. As the number of straight segments is increased, the capacitance required for each straight segment decreases, since the total net capacitance asymptotically approaches a limit for an infinite number of straight segments.

For a practical lowpass birdcage operating at a high frequency and/or large volume, the single capacitor of value C in each segment is replaced by a number M of capacitors of value MC spaced evenly along the whole length of the straight segment. The net capacitance per strip is retained. This reduces electric field concentrations that create excess dielectric losses in the sample and eliminates the possibility of coronal breakdown. At high frequencies, the length of the straight segment may be a non-negligible fraction of the wavelength. In that case, the inclusion of multiple evenly spaced capacitors effectively increases the phase velocity of the straight segment. The wavelength is increased in that direction so the current is essentially constant along the whole length of the straight segment.

3.2 Generalized Forms of the Birdcage Resonator

The lumped element delay line may be thought of as a chain of repeating elements. Each element is a lowpass LC filter which generates a frequency dependent phase shift. The resonant condition corresponds to each repeat element adding a phase shift equal to $2\pi m/N$. For the lowpass birdcage, the phase shift per repeat unit increases with increasing frequency. Hence as a generalization, any chain of phase shifters or coupled resonant circuits can develop the desired sinusoidal current distribution. The highpass birdcage [Figure 1(b)] is so named because each repeat element forms a highpass LC filter. For a highpass birdcage, the phase shift per repeat unit decreases as the frequency increases. Hence, in the highpass birdcage, the frequency of each $\sin m\theta$ mode decreases as m increases. In addition to the transverse modes, the highpass birdcage has axial modes. These modes correspond to resonance currents in the endrings with no current along the straight segments. There can be a corotating mode and counter-rotating mode wherein the current circulating in one endring is either in

phase or out of phase with the current in the other endring. The axial modes usually occur at higher frequencies than the desired homogeneous modes.

For the homogeneous $\sin\theta$ mode of the highpass resonator, the endring capacitors on one side of the ring are essentially connected in series. But the net capacitive impedance is not a simple sum of the individual impedances because each capacitor has a different current and different electrostatic energy storage. The advantages of distributing the large induced voltage across multiple capacitors are intrinsically incorporated in the highpass design. As the number of straight segments is increased to improve field homogeneity, the number of capacitors must be increased proportionally. But the capacitive value of each capacitor must also be increased disproportionately. The net effective capacitance of the series-connected capacitors must also be increased to accommodate the decrease in inductance with an increasing number of straight segments. Hence, there is a practical limitation to the number of straight segments that can be utilized in a highpass birdcage.

3.3 Differences Between Highpass and Lowpass Birdcages

The fundamental difference between the highpass and lowpass birdcages arises from the wave nature of time-varying electromagnetic fields. Although it is possible, in principle, to make a uniform static magnetic field, it is not possible to make a uniform time-varying magnetic field. The wave equation requires a spatial variation due to the vector wavenumber $\mathbf{k}$, or inverse wavelength, which is determined by the dielectric constant and magnetic susceptibility of the medium. The highpass and lowpass resonators have different directions for $\mathbf{k}$ in the volume. Consider the case of a very long birdcage structure where the field contributions of the endrings can be ignored. Operating in the $\sin\theta$ mode, the long highpass resonator resembles a set of twin-lead parallel-wire transmission lines along the z direction. Each wire carrying current of the top half of the cylinder is paired with a wire on the bottom half carrying current in the opposite direction. Because the endring network terminates both ends of this long composite transmission line symmetrically, it supports a standing wave along the z direction. The surface current is proportional to $\sin\theta \cos k_z z \sin\omega t$, where k_z corresponds to wavelength at frequency ω and is determined by the average dielectric constant in and around the birdcage. For a birdcage whose diameter is small compared with the wavelength, the transverse field is approximately proportional to $\cos k_z z \sin\omega t$ in the x direction. Applying Faraday's law gives a transverse electric field in the y direction proportional to $\sin k_z z$.

The long lowpass resonator must have many capacitors evenly spaced along each wire to tune out the inductive impedance between each capacitor. The resulting composite transmission line generates no phase shift along the z direction at the resonant frequency. The current is uniform along z , therefore k_z is zero. However, k_y is not zero. Hence, the transverse rf field is still in the x direction but is proportional to $\cos k_y y \sin\omega t$. The time-dependent $\mathbf{B}$ -field generates a longitudinal electric field along the z direction proportional to $\sin k_y y$. For both highpass and lowpass resonators, the electric fields are directed parallel to the distribution of capacitors. The electric field is large near the capacitors and diminished to zero at the center of the coil and reverses direction and

becomes large at the other side or end of the coil. There is a nearly linear gradient in the electric field strength for coils of modest size compared with the wavelength. The different directions for the electric field in the highpass and lowpass resonators can determine which is more suitable for a given application.

3.4 Imperfect Birdcage Resonators

The preceding treatment was for ideal birdcages with full N -fold rotational symmetry. Difficulties arise when the symmetry is broken. Typically, the geometric layout of the conductive runs can be controlled sufficiently accurately to maintain the required symmetry. But the capacitors will usually have a distribution of values around the nominal value. Random fluctuations in the value of capacitance applied around the birdcage destroys its symmetry and perturbs its operation. Tropp provides a mathematical treatment of the perturbed coil performance³. The following treatment gives a simplified discussion of small, accidental perturbations as well as an example of a deliberate major perturbation. For small perturbations, the current distributions are assumed to remain sinusoidal but the resonant frequencies and directions of the two homogeneous modes may be shifted. Even small perturbations are therefore detrimental to quadrature operation of the resonator. Large perturbations such as cutting the endrings will drastically alter the current distribution.

Consider a lowpass birdcage with all capacitors having equal values except that the one capacitor located at $\theta = \beta$ is incremented by δC . For this situation the two natural modes have current distributions proportional to $\sin(\theta - \beta)$ and $\cos(\theta - \beta)$. The frequency for the $\sin(\theta - \beta)$ mode is unchanged because none of its current flows through the perturbed capacitor. The perturbation is invisible to this mode. In contrast, the $\cos(\theta - \beta)$ mode is affected by the change in capacitance because that mode has its current maximum in that capacitor. This mode stores electrostatic energy in the perturbed capacitor. The frequency of the $\cos(\theta - \beta)$ mode shifts up or down for a negative or positive value of ΔC , respectively, because the total effective capacitance of this resonant mode is altered. The two homogeneous modes no longer have the same frequency. This is called a splitting of the degenerate modes. The two modes still produce fields that are orthogonal in direction to one another, but the orientation of the two modes is no longer arbitrary. The position of the perturbation determined a preferred orientation for the coordinate system.

For the more general case, where there is a few percent random scatter among all the capacitor values, the $\sin(\theta - \alpha)$ and $\cos(\theta - \alpha)$ modes become oriented so the lower-frequency mode experiences a maximum effective net capacitance and the higher-frequency mode activates a minimum effective net capacitance. In general, there is a continuous range of possible values for the orientation α even though the straight segments are located at only a discrete set of angles. If the frequency splitting is large compared with the linewidth of the two resonances, operation of the coil in quadrature will be very difficult because only one or neither mode will be driven at its resonant frequency. Even if the two drive points are aligned along the natural orientations, α and $\alpha + \pi/2$, of the two perturbed modes, the induced currents will usually have different magnitudes and erroneous phases.

As an example of a major perturbation, consider a birdcage knee coil that is constructed so the top half is removable for easy positioning on the patient. Each endring is cut at $\theta = 0$ and π , and is not reconnected electrically when the top half is repositioned. The $\cos \theta$ mode has no current in the endring at these points normally. The cuts are invisible to this mode, which therefore can produce a homogeneous linear field along the y axis at the original unperturbed frequency. However, the former $\sin \theta$ mode is destroyed because it would require a current maximum where the endring conductors are removed. A new mode appears with current proportional to $\cos \theta$ on the top half and proportional to $-\cos \theta$ on the bottom half. This mode requires no current in the endring at the cuts, and, in fact, creates a discontinuous voltage step across the cuts. The resulting counter-rotating currents in the two halves of the birdcage resonate at a frequency about 10% higher than the remaining homogeneous mode. Such a disjoint coil cannot be operated in quadrature.

3.5 Rf Shields

The rf body coil is placed inside the magnet bore in close proximity to three or more gradient coils. Gradient coils are audiofrequency devices with multiple turns in overlapping layers. Such constructions can contain many spurious resonances which will absorb rf power and detune an enclosed rf resonator. Generally, an rf shield is placed between the rf coils and gradient coil to isolate the rf coil from the gradient coils and the rest of the outside world. The shield must be opaque to rf fields but transparent to the switched gradient fields. The shield generates rf surface currents that deflect any perpendicular component of the impinging rf magnetic field. The shield currents tend to flow in the opposite direction to the primary currents in the coil. Therefore, the shield cancels part of the field in the sample volume but strengthens the field in the space between the coil and shield. The shield reduces the inductance of the birdcage and raises its frequency significantly. The flux that exits one side of the coil is squeezed into a confined area as it returns to the opposite side of the coil. The energy density in the sample volume is reduced and the energy density outside the sample volume is increased. Hence, the shield will drastically reduce the filling factor as its diameter approaches that of the coil. For a shield 10% larger in diameter than the birdcage, more than 80% of the rf magnetic field energy is outside of the sample volume. Because whole body tissue losses are high at 1.5 T, the poor filling factor does not greatly reduce the signal-to-noise ratio at this frequency. At lower frequencies or smaller sample volumes, the shield can adversely affect the signal-to-noise ratio. Because gradient amplifier power requirements increase as the fifth power of gradient coil radius, there is an inherent disincentive to enlarge the space between the rf coil and the gradient coil.

The shield can simply be a cylindrical shell of copper foil no more than four or five rf skin depths thick. To prevent degradation of gradient field rise time, the shield should be divided up with slits into long narrow segments that run essentially parallel to the induced rf currents. Rf bypass capacitors interconnect shield segments wherever rf current must cross a slit.

4 BIRDCAGE DESIGN CONSIDERATIONS

The underlying assumption of the following sections is that a researcher can build a birdcage for a particular application faster by making a series of experimental prototypes than by starting with an extensive theoretical or computational analysis.

The initial required design decisions include determining the overall size, number of repeat elements, width of conductive elements, mode of coupling to the transmitter/receiver, need for a shield, choice between highpass or lowpass, and choice between quadrature or linear operation. The diameter chosen should be no bigger than needed to accommodate the desired sample or subject without touching the side walls. Excessively large diameters would decrease the filling factor and add coil losses. If the tissue losses are much bigger than the coil losses, then the filling factor is good enough. The length of the birdcage controls the major source of field inhomogeneity. Measured along the central axis of the cylinder, the rf field strength begins to decrease significantly within a distance of one coil radius from the open ends. At the plane of the endring, the rf field on the axis has fallen to about one-half the strength at the center of the coil. The choice of length for the birdcage is an engineering trade off between improved field homogeneity and increased noise from portions of the sample not being imaged. Obviously the rf field need not be homogeneous in a volume bigger than the homogeneous region of the static magnetic field B_0 .

The size and shape of the conductive paths determine the effective coil inductance. Copper foil is a good choice for conductors in a birdcage where there is limited clearance between coil radius and shield. The width of the straight segments is limited by the need for the surface to be transparent to the exiting transverse field. Equal widths of copper foil and air space have worked well enough. The width of the endring has a major effect on the total inductance of the birdcage because of larger current carried on the endring compared with the individual straight segments. The endrings should be several times wider than the individual straight segments. Low inductance means lower voltage and less detuning by stray capacitance.

In choosing between the highpass or lowpass configuration, the principal factor is how the shape of the subject effects stray capacitance between the subject and the coil. Shunting electric fields through tissue or a conductive sample detunes and loads the coil. For example, placing the patient's arms close to the capacitors in the straight segments of a lowpass body resonator will disproportionately load and detune the vertical mode and degrade the quadrature operation of the coil. The patient's shoulders being close to the endring of a head or body birdcage will affect the highpass but not the lowpass birdcage. Practical limitations on the values of capacitance available may dictate the selection of highpass or lowpass. For example, at low frequencies the endring capacitors in a highpass resonator might become unacceptably large. In contrast, the capacitors on a lowpass resonator are inherently smaller, especially when the number of repeat elements is increased. The choice of the number of repeat elements is a trade off between the short-range inhomogeneity generated and the number of components required. The regions of inhomogeneity extend radially inward for a distance comparable to the distance between segments. Sixteen repeat elements is a reasonable compromise.

The most direct way to determine whether an rf shield is required is to observe what happens to lineshape and frequency as a prototype coil is inserted in the magnet bore. Line broadening or position-dependent frequency shifts indicate a shield is needed. A shield will probably be required unless the new coil is much smaller than the bore diameter. Because it shifts the resonant frequency, the shield must be considered as an integral component of the overall coil design and construction. Without a shield, the tuning of the two modes for quadrature operation may not track as the coil is positioned in different places within the magnet bore.

The chief advantage of linear operation is greater simplicity of construction, tuning, matching, and operation. Initially a resonator can be operated linearly to determine the feasibility of an experiment. It can be converted to quadrature if the advantages justify the increased complexity. The advantages include a reduction in rf power amplifier capacity, lower power deposition, increased signal-to-noise ratio or shorter data acquisition time, improved field homogeneity by averaging the nonuniform currents in the endrings, and removal of the azimuthal angle dependence of rf penetration effects in the patient.

The resonator can be connected to the transmitter/receiver by capacitive or inductive coupling techniques (see *Radiofrequency Systems and Coils for MRI and MRS*). Capacitive coupling requires applying a voltage across one or more of the birdcage's capacitors. Directly connecting cables to the birdcage tends to break the symmetry of the birdcage and detune the two quadrature modes. Isolating the cables' grounds with baluns is only partially effective. Inductive coupling through an air gap avoids some of the ground isolation issues. The inductive loops can be linked directly to the transverse flux entering at the cylindrical wall. If an inductive loop is tuned to self-resonance when isolated, moving it close to a birdcage will vary the matching without significantly detuning the birdcage. Alternatively, the inductive drive can intersect the return flux where it is concentrated between the coil and the shield. Inductive coupling is usually more convenient.

5 CONSTRUCTION TECHNIQUES

To construct a birdcage requires equipment for observing its frequency spectrum such as a network analyzer, a spectrum analyzer with tracking generator, or a variable-frequency signal generator plus an oscilloscope. A small inductive loop connected by cable to the signal source is placed close to the edge of one endring of the birdcage. As the frequency is swept, the resonator is excited for all modes that carry current in the endring near the driven inductive loop. A second small inductive loop connected to the receiving device can be used to observe the strength and orientation of the generated field.

Initial construction starts with laying out the foil conductive strips on an appropriately sized nonconducting substrate. A hot glue gun is convenient for attaching the copper foil. A narrow cut is made in each straight segment for a lowpass, or each repeat segment of both endrings for a highpass. A relatively large-valued capacitor is soldered across each gap. These test capacitors should be premeasured to ensure they are all nominally equal in value. The frequency spectrum of the birdcage is observed for several positions of the drive loop with the shield

in place, if used. All transverse modes except the two desired homogeneous modes should be zero near the central axis. To confirm that the number of repeat elements and the length are large enough to give the desired region of homogeneous B_1 , the homogeneous modes should then be further probed.

Generally the two homogeneous modes will differ in frequency by a few percent or less but both will be well separated from the other modes. Presumably, the average homogeneous frequency measured is low enough so there are no significant stray capacitance or wavelength effects. To change the resonant frequency to the Larmor frequency, calculate the new capacitor value as the old capacitor value times the old frequency squared divided by the new frequency squared. No dimensional changes to the foil layout that alter its inductance should be made hereafter. Replace each of the capacitors with the new calculated value. Trying to pull the frequency by a large amount by changing only one capacitor will degrade the homogeneity. If a lowpass resonator is being constructed, additional cuts can be spaced along each straight segment; proportionally larger-valued capacitors are applied to each cut to generate a net series capacitance equal to the calculated value.

Fine tuning is needed to align both desired modes to the same frequency. In principle, only two capacitors need be changed to eliminate the frequency splitting³. Alternatively, four variable-trim capacitors can be added at 45° intervals on one side or endring. By deducing from the orientation of the split modes which capacitors carry the largest currents, the variable capacitor nearest each current maximum can be appropriately adjusted. Iteration is required, but the inductive pickup loops must be repositioned frequently because the modes shift orientation as the splitting decreases. Four variable capacitors rather than one for each repeat element should be sufficient to reduce the splitting to a small fraction of the loaded linewidth. If linear operation is acceptable, a major perturbation will lock the remaining linear mode in a well-defined position where it can be more easily tuned.

6 ADDITIONAL INFORMATION

Because birdcage resonators were initially developed commercially, the original patents provide extensive discussions of the properties, homogeneity, fabrication, and rf shielding of birdcage resonators.⁴⁻⁶ Another patent describes the use of conductive endcaps to reduce the roll off of rf field strength at the ends of a birdcage.⁷ Joseph and Lu discuss tuning the two homogeneous modes of a highpass resonator to two different frequencies for imaging both protons and fluorine.⁸

Mathematical and empirical treatments of the spectrum of the birdcage have been given by several authors.⁹⁻¹¹ The periodic structure of the birdcage resonator has analogies in other branches of science and engineering. For example, if a lowpass resonator is made with large capacitors in the even-numbered straight segments and small capacitors in the odd-numbered ones, the spectrum has a low-frequency branch and a high-frequency branch corresponding to the acoustical and optical vibrational lattice modes of an ionic crystal. Such a resonator could in principle give quadrature excitation at two frequencies. Other forms of the dual-tuned quadrature birdcage utilize dual tuning of each repeat element¹² or combine more than one birdcage on the same cylinder (see *Multifrequency Coils for*

Whole Body Studies). A spherical volume of uniform rf field can also be generated using principles similar to the birdcage.¹³

1 INTRODUCTION

Internal coil placement may allow smaller coil size and/or closer positioning than is possible for a conventional externally located coil. Although it is conceivable that any magnetic field needing generation or detection could be served by internally placed coil(s), this article considers only coils used for detection of the NMR signal. Such internally placed receiver coils

have been the subject of substantial attention by several research groups during the past dozen years. This attention is driven by two potentially substantial advantages associated with reduced coil size and/or distance from subject: (1) increased signal to noise ratio (SNR), and (2) reduced aliasing. The SNR is a fundamental limiting factor in the quality of many clinical studies, and increasing the probe SNR performance may allow better resolution and/or shorter acquisition time. Aliasing may compromise the ability to obtain images of a small target within a larger object, which may in turn also have consequences affecting resolution and/or acquisition time.

The performance advantages of internal coils are conceptually identical to those associated with tailoring the size and location of the receiver coil to the target region by using a 'surface coil' or other external specialty coil (see Related Articles).¹ 'Surface coils' are now routinely used in clinical whole body NMR imaging, whereas internal coils, although conceived relatively soon after the birth of the surface coil, have not yet been established in similarly widespread use (see Table 1, and Related Articles). Currently, disposable internal coils designed for three different target anatomic areas are available for operation at 1.5 T and 1.0 T on a number of different MRI system platforms. Coils optimized for prostate, cervical, and colorectal studies are available; all are designed for endorectal insertion. Repeated use coils have been offered

by two MRI system manufacturers for use on their own systems. In light of the standard arsenal of five to ten surface coils at a typical clinical MRI site, the relatively slow rate of development and adoption of internal coils may be attributed to a reluctance to make MRI an 'invasive' procedure. Another barrier is that currently dominant clinical uses for MRI (imaging of the brain, spine, and musculoskeletal system) are not obvious candidates for improvement by use of internal coils, so that the burden of proving new applications is carried simultaneously with probe development efforts.

The current status of the proposed uses of internal coils, as listed in Table 1, is somewhere between proof of feasibility and reasonably informed judgment of the relative costs and benefits. Accurate assessment of potential benefit requires knowledge of ideally achievable performance, which is still an open question. Estimating potential performance, as well as answers for some unique challenges associated with obtaining that performance in practice, involves a body of engineering problems. These problems, together with some current solutions, are presented in the remainder of this article.

2 SPECIAL CONSIDERATIONS IN THE DESIGN OF INTERNAL COILS

Although a particular application may have its own unique design constraints, there are a few general considerations which characterize internal coils as a class, based on differences with current conventional external magnetic resonance (MR) probes.

2.1 Size

The limited space which is available for locating and/or inserting coils imposes size constraints. For endorectal imaging, mechanisms have been designed to expand the coil after insertion by inflation with air from an external source. Several methods have been devised, including direct inflation of a balloon containing the coil, and inflation of an inner balloon with the coil itself affixed to an external balloon of an optimal shape and size.

In addition to size constraints on the coil windings and substrate, the limited 'real estate' may impose a size limitation on the number and size of capacitors, cables, insulating layers, sterility barriers, and other probe components. Because of the inherently close coupling to the sample and other tissue material, capacitive and inductive sample 'loading' can be expected to dominate noise considerations down to relatively small conductor sizes (at currently popular high operating frequencies, e.g. 64 MHz); however, at some point of miniaturization and/or lower operating frequencies, these losses may become significant. Resistive losses in connecting cables will show a similar trend (increasing losses with smaller size); note that these losses will generally increase with higher operating frequencies, and for connection schemes that do not implement the connecting cable as a nonresonant transmission line operating at its characteristic impedance.

At moderate sizes, such as endorectal applications, capacitor size is not a dominant issue; standard series of high Q capacitors are available in capacitance of up to 100 pF at sizes of the order $2 \times 2 \times 2$ mm. At much smaller probe sizes, such as for

intravascular application, this size is too big; unfortunately, achieving the same capacitance at smaller size requires a compromise in breakdown voltage (related to plate spacing) and/or loss of circuit and coil Q due to increased losses in the dielectric material between the capacitor plates. This issue is compounded by the reduced inductance of smaller coils, which require larger capacitance to achieve resonance.

2.2 Shape

Conventional external probe design locates the coil in a region of approximately free space (typically, the air around the patient), with the target region either inside or adjacent to this free space; because it does not contribute either signal or noise, the probe designer may essentially ignore the free space, and use all available degrees of freedom to construct a desired response in the target region. In contrast, the internal probe is immersed in material which contributes both signal and noise. Any unnecessary noise contribution is, of course, never desirable; the unnecessary MR signal may be harmless, or may be a detriment due to aliasing, depending on the desired field-of-view.

For some applications, such as imaging of the prostate from inside the rectal cavity, the coil is adjacent to the target region, and the probe sensitivity design problem is similar to that of a 'surface coil'; this situation is well served by some version of a loop coil of linear design; quadrature and array coils are difficult to implement in an effective manner in the confined space, and with the variable shape. Inflatable balloon endorectal coils have been customized for specific targets. To optimize coil operation in the prostate area, the coil balloon can include a saddle-shaped surface to surround the bulge containing the gland. This enhances probe operation in two ways. First, the coil itself is more readily placed in the immediate region of the gland; second, the probe is retained in correct alignment following inflation due to the conformal nature of the balloon structure. Probe coils for imaging the cervix from an endorectal location can include a flatter, wider balloon shape, and a means for remotely steering the probe assembly into the proper position relative to the target anatomy. For colon imaging, the coil is generally centered in the balloon structure to provide a uniform degree of sensitivity around the probe structure.

For other applications, such as intravascular arterial imaging, the target region partially or completely surrounds the coil, giving a novel perspective to probe sensitivity patterns. This has led to consideration of several novel coil winding patterns. An opposed solenoid configuration, as shown in Figure 1, has proven useful in imaging an annular target region around the coil, with remarkable homogeneity in axial planes between the two solenoids.

2.3 Getting the Signal Out

For external coils, the standard way of transferring the NMR signal from the probe to the rest of the receiver is via a coaxial cable or other transmission line structure. This is not necessarily appropriate for internal coils, due to the size of such cable, and is further complicated by the cable running through lossy and NMR-signal-generating media on its way out of the body. Several coupling schemes which attempt to deal with these considerations are shown in Figure 2.

Figure 1 Magnetic field pattern for a pair of opposed solenoids. Note that with the probe aligned along B_0 as shown, there is a region of relatively high sensitivity and homogeneity, in a plane between the two solenoids. Note also the pair of approximate null planes (— · —) where the opposed solenoid field is essentially parallel to B_0 , with negligible B_{xy}

The scheme shown in Figure 2(a) utilizes a balanced transmission line, ideally operating at or near its characteristic impedance. This will minimize the VSWR (voltage standing wave ratio) on the transmission line, and thus minimize associated losses. However, due to the electric field of the balanced transmission line, proximity to surrounding tissue may cause significant losses. A similar approach, shown in Figure 2(b), uses an unbalanced coaxial transmission line rather than twisted pair, which reduces such losses, assuming the circuit achieves negligible signal currents on the outside of the cable shield conductor.

Figure 2(c) illustrates a wireless inductive coupling similar in concept to that sometimes seen with external probes. In an internal application, lossy tissue in the space between the primary and secondary coils can make this a suboptimal solution. Inductive coupling with both coils internal to the probe assembly is typically precluded by space considerations.

Figure 2(d) illustrates a means to employ a locally mounted preamplifier. With sufficient signal gain from this amplification, the losses in the transmission line become negligible; the coupling scheme SNR performance is then essentially determined by the noise figure of the amplifier active device as implemented.

Figure 2(e) describes a method to locate a high impedance field effect transistor (FET) preamplifier at a substantial distance from the coil, while retaining many of the advantages of 'local' placement. The coil itself acts as a series resonant circuit, with impedance transformation accomplished by a one-quarter wavelength output cable. Due to the high VSWR on the cable, the losses are greater than those for a direct connection to a parallel resonant coil; however, this scheme offers several practical advantages, as discussed in the following section.

Figure 2 Several different tuning/matching/coupling schemes which have been used for internal coils: (a) parallel resonant probe coil, with balanced capacitive coupling to a balanced transmission line; (b) parallel resonant probe coil, with capacitive balun match to unbalanced transmission line; (c) parallel resonant probe coil, with wireless inductive coupling; (d) parallel resonant probe coil, with coupling via a field effect transistor active device; (e) series resonant 'transmission line' coil, with quarter-wave line coupling and diode switch. The component values given are for different operating frequencies: (a) 97.3 MHz; (b) 97.3 MHz; (c) 81 MHz; (d) 64 MHz; (e) 64 MHz

3 COMMERCIALY PRODUCED ENDORECTAL COILS

Internal coils for prostate, cervical, and colorectal imaging at 1.5 and 1.0 T have been commercially available since 1991 [Medrad; Indianola, PA, USA]. These endorectal coils are disposable and designed for single-use applications to avoid the problems associated with re-use. The coils have similar internal electronics, but component and mechanical variations depending upon application. Interface devices are available for use with a variety of host MRI systems and also to allow the endorectal coils to be used in combination with external phased array coils to improve coverage and utility.

To reduce the product cost to a level compatible with a single-use, disposable probe, some design decisions were made concerning the configuration of the endorectal coil and the associated interface device. The disposable endorectal coils themselves are designed for a specific target anatomy and operating field strength only. Differences in various commercial MRI systems, operating frequencies, and the hardware needed to manage utilization with existing external phased array coils are accommodated in a separate re-usable interface device; it contains the majority of the electrical components. Figure 2(e) shows the decoupling diodes and tuning diode that are part of the interface device connected to the endorectal coil.

3.1 Coil Design

The coil itself is constructed from approximately 23 cm of coaxial cable, retained in an appropriate shape by the outer balloon of the probe assembly. The coaxial shield conductor is opened halfway around the loop. In this ‘transmission line’ design, the coaxial shield may be conceived as a Faraday shield, which provides some balancing effect on the coil, and reduces the level of rf currents flowing on the outside of the output coaxial cable. The coil is series resonated to the approximate operating frequency by a single series capacitor; this capacitor, and the coil conductor, are the only electrical components on the disposable probe itself.

3.2 Coupling and T/R Decoupling

Signal is extracted via a one-quarter wavelength coaxial cable, as shown in Figure 2(e). This simple arrangement serves two needs: (1) the series resonance of the probe coil is transformed to a parallel resonance at the end of the cable, thus providing an appropriate source impedance to drive a low-noise FET preamplifier; and (2) it affords transmit/receive decoupling by placing an rf short at the output end of the $\lambda/4$ cable, with the short inverted by the cable to a high impedance at the coil end, thus effectively opening the loop of the coil during transmit excitation. The rf short is accomplished by using either crossed rf switching diodes, or a selectively-biased p-i-n diode within the interface device.

3.3 Interface to the Scanner Surface Coil Input

Because the endorectal coil is a volume-produced disposable device and is usually inflated after insertion into the patient, the tuning of the coil may benefit from optimization on a per-coil and per-patient basis. Some interface devices include an electronic circuit to accomplish this automatically; the tuning is done by applying an optimized DC potential to the varactor diode shown in Figure 2(e). With the advent of low-noise preamplifiers having very low input impedance in most MRI systems, the need to perform the per-use tuning can be negated by proper interface circuit design. To accomplish this, a network is employed that tunes the nominal endorectal coil under average loading conditions to appear as a 50 ohm resistive source. The electrical length from the signal output end of the one-quarter wavelength (76 cm) cable, which is part of the endorectal coil, to the input of the low impedance preamplifier

is an integer multiple of one-half wavelength; this allows the endorectal coil to provide the proper source impedance to the low-noise preamplifier; it also allows the low impedance of the preamplifier both to isolate and to broaden the tuning of the endorectal coil. This is especially beneficial when using the endorectal coil as one coil of a phased array set of coils.

3.4 Coil Array Combinations

More recent developments enable the family of endorectal coils to be used with pelvic or torso array coils. New versions of the interface device provide a network to combine the signals from the two posterior coil elements in the four element torso or pelvic array coil (Signa, GE Medical Systems, Milwaukee, WI; MR Innervu, Medrad, Indianola, PA), thus creating an available phased array input port for the endorectal coil signal. The results include a substantial improvement in image SNR (see Table 2) relative to the body coil, torso array, or pelvic array alone, along with substantially greater image uniformity relative to the endorectal coil alone.

3.5 Ongoing Developments

Presently, several development programs are underway to expand the utility, functionality, performance, and capabilities of commercially available endorectal and intracavity coils. Projects in process include spectroscopic applications, quadrature and array probe coils, re-usable probes and coils, and additional field strengths.

4 COMPARISON OF SNR FOR INTERNAL AND EXTERNAL COILS

To decide if it makes sense to use an internal coil rather than an external coil in a particular application, it would be helpful to have a measure of relative performance. Two common performance indices for conventional receiver probes are SNR and homogeneity. For ‘surrounding’ coils like solenoids or saddles, the homogeneity in the region of interest is relatively high; this means that SNR is well represented by an average value over a region of interest (or even a single measurement at the center of that region), and homogeneity can be represented by a single number expressing the range of intensities (normalized by the average value). Due to extreme proximity of sample and coil, the homogeneity of internal coils is typically much less than surface coils (which are themselves much less homogeneous than surrounding coils); with decreasing homogeneity, accurate and meaningful measurement of the SNR or homogeneity is not so straightforward. Furthermore, selecting an appropriate external coil used for reference is problematic, for two reasons: (1) defining an ‘optimum’ single external coil requires exact definition of many variables, including proximity to surface and size of target region; and (2) an array coil configuration, such as are currently entering routine clinical use, may supersede a single surface coil as an ‘optimum’ external reference standard.

Bearing in mind these caveats, it is instructive to survey reported SNR improvements obtained using internal coils. As shown in Table 2, this improvement in SNR can be as small as two-fold (applied to imaging the lumbar spine of a cat), and as

Table 2 Comparison of SNR for Internal and External Probes^a

Internal coil	Subject	External coil	Relative SNR (int./ext.)
Circular loop, $d = 2.5$ cm; inductive coupling; around subject	Phantom	Spherical, $d = 25$ cm	4.2
Solenoid, $d = l = 1.5$ cm; inductive coupling; immersed/implanted	Phantom	Birdcage, $d = 6$ cm	~ 10
Opposed solenoids, $l \approx 4d = 20$ mm; FET or capacitive coupling; immersed	Rat kidney		
	Phantom	Loop, $d \approx 10$ cm	~10
Elliptical loop, 8.5×4.5 cm; capacitive coupling; phantom adjacent to loop; inflatable, endorectal	Phantom	Body coil (quadrature), $d \approx l \approx 50$ cm	2
Rectangular loop, 3×8 cm; capacitive coupling; inflatable, endorectal, commercial	Phantom	Body coil (quadrature; commercial)	5
Above, plus pelvic array	Phantom	Pelvic array (commercial)	3.5
Rectangular loop, 5×4 cm; capacitive coupling; inflatable, endorectal	Human prostate	Body coil, $d \approx l \approx 50$ cm	13
Half-saddle loop, $3 \times 2 \times 1.2$ cm; inductive coupling; surgically implanted	Cat, L1–L3	Loops, 4×6 cm; quadrature (surface coil)	1.32

^a d , Diameter; l , length.

large as 10-fold (as found for intravascular phantoms). For human endorectal imaging, the observed gains in image SNR at the target anatomy range from three to eight times the performance of alternative coils such as the body or torso array coils.

Cryogenic Magnets for Whole Body Magnetic Resonance Systems

David L. Rayner, Peter J. Feenan, and Rory J. Warner

Magnex Scientific Ltd, Abingdon, Oxon, UK

1 INTRODUCTION

One of the most critical parts of the instrumentation in a magnetic resonance (MR) system is the magnet, which tends to be an expensive high technology item. Cryogenic (superconducting) magnets were first used in MR systems in the early 1980s,¹ and have since become the preferred type of magnet system for most users. This is largely because they possess the advantage of being able to operate at high field strengths (potentially up to 10 T in some configurations), with excellent time dependent field stability.

The main features of a superconducting magnet for MR applications are the superconducting coils, the cryogenic container (cryostat), the method of field homogeneity control (field shimming), and, where necessary, the method used to confine the magnet's fringing field. All these features are discussed in detail in this article, together with information on special high field superconducting magnet systems and systems designed for mobile MR applications.

The design of MR magnet systems has advanced considerably since the earliest 0.35 T versions were introduced. Today's systems are normally designed to be operated at a fixed field strength of either 0.5, 1.0, 1.5, or 2.0 T, and to have a clear room-temperature bore (before the introduction of gradient coils) of 80–100 cm. Most systems of this type are screened to reduce the fringing fields and today have relatively short 1.5–1.7 m bore length. After introduction of the gradient coils and rf body coil, the patient access is reduced to 55–65 cm (see *Gradient Coil Systems* and *Radiofrequency Systems and Coils for MRI and MRS*). A typical 2.0 T whole body superconducting MR magnet system is shown in Figure 1.

Higher-field magnets have been introduced in the late 1990s that operate at field strengths of 3.0 T, 4.0 T, and even as high as 8.0 T (with an 80 cm bore). In addition, the last few years have seen the increasing popularity of open-aspect, low-field (0.2–0.35 T), magnets. These magnets, which depart from the cylindrical format, give greater access to the patient through gaps in the structure. Most open-aspect magnet systems utilize permanent magnetic materials and operate in the field strength range 0.2–0.25 T; however, systems operating at 0.35 T have also been introduced that utilize superconducting driver coils. Higher field strength (greater than 0.5 T) open-access magnet systems are already in an advanced stage of development and are expected to be commercially available within a few years.

The 1990s have also seen an increase in the demand for MRI magnet systems for interventional or minimally invasive surgical studies. One of the magnet design solutions chosen to address this application is the split pair or 'double doughnut' superconducting magnet system. These systems are of standard cylindrical geometry but the magnet and cryostat are split into two halves and are separated such that the clinician or surgeon can gain access to the patient through the split. Field strengths for these types of system are generally limited to 0.5 T.

2 MAGNET DESIGN

Cryogenic (superconducting) magnet systems rely on the physical phenomenon of superconductivity,² whereby certain materials behave as if they have no measurable dc electrical resistivity when they are cooled below what is defined as their 'critical temperature'. The wire used in the construction of such magnets is normally niobium-titanium (NbTi) which has a critical temperature of approximately 10 K and consists of a number of filaments of NbTi embedded in a copper stabilizing matrix. Most whole body superconducting MR magnets are wound from NbTi and are designed to operate in a reservoir of liquid helium boiling at a temperature of 4.2 K.

The magnet consists of a group of coaxial coils, the positions and number of turns of which are carefully chosen to produce a homogeneous field region at its center.³ The coils are electrically connected together in series, and a complete circuit is formed with a superconducting switch. The switch consists of a short length of superconducting wire which is in close contact with a heating element. When the heater is on, the switch is warmed above its critical temperature and there is no longer a continuous superconducting circuit. Under these conditions the switch is said to be 'open', and current can be run into the magnet windings using a dc power supply. When the current flowing through the magnet is such that the central field is at the required value, the switch heater can be turned off. The switch quickly cools, becomes superconducting and so forms a continuous superconducting circuit. The switch is now referred to as being 'closed', and the power supply can be removed, leaving the current flowing in the magnet. The magnet is now operating in the persistent mode and will have a field stability of typically better than 0.1 ppm h⁻¹. A simple superconducting magnet circuit is shown schematically in Figure 2.

Figure 1 A 2.0 T whole body superconducting MR magnet system

Figure 2 Schematic drawing of a superconducting magnet circuit

In the event of an emergency it may be necessary to de-energize the magnet within a few seconds. Special heaters placed in good thermal contact with the magnet windings are generally provided for this purpose. The heaters are driven by a device known as an emergency run-down unit (ERDU). When the ERDU is operated, the heaters warm part of the magnet windings above their critical temperature and thus out of the superconducting state. Once part of the magnet windings are resistive they are further warmed by ohmic heating and the current quickly decays. The heat generated by the magnet causes the liquid helium surrounding it to evaporate and the evaporated gas is quickly expelled from the cryostat. This process is referred to as a 'quench'.

In order to avoid damage to the magnet windings occurring during a quench, a protection circuit is normally employed.⁴ This circuit, which typically consists of resistors or diodes, is connected in parallel across the magnet or individual sections of the magnet windings, and prevents excessive heat generation within the windings from occurring. The protection circuit is also used to prevent potentially harmful high voltages being generated within the windings.

3 CRYOSTAT DESIGN

The liquid helium vessel containing the magnet needs to be thermally isolated from room temperature, and therefore the three principal mechanisms of heat transfer (convection, conduction, and radiation) need to be minimized.

Heat transfer via convection is almost completely eliminated by evacuating the cryostat. The external structure of the cryostat which contains the vacuum is normally referred to as the 'outer vacuum container' (OVC). Heat conduction from the OVC to the helium vessel is minimized by ensuring that the internal mechanical supports for the helium reservoir are long, of small cross-section, and made from materials of low thermal conductivity. Stainless steel, titanium and glass-reinforced plastic (GRP) are commonly used materials for the internal suspension of the cryostat. Radiation from the OVC to the liquid helium vessel is intercepted with radiation shields. Normally there are two shields which completely surround the helium reservoir. These shields can be cooled by one of two

methods. Some cryostats utilize two-stage cryorefrigerators,⁵ with each stage being thermally linked to one of the radiation shields. The cryorefrigeration system is based on the Gifford-McMahon principle using a closed helium gas cycle. The system comprises an expansion chamber, often referred to as a 'cold head', connected via high pressure gas lines to a compressor. The cycle works by allowing the helium gas to expand and cool in the expansion chamber. The helium gas is circulated to a compressor and the heat is removed from the system as the gas is recompressed. By this method typical inner and outer radiation shield temperatures of 20 and 80 K, respectively, are achieved.

Alternatively, some cryostats are designed with an integral liquid nitrogen reservoir which is used to serve as the outermost radiation shield and is maintained at the boiling point of liquid nitrogen (77 K). The inner radiation shield is thermally linked to part of the neck portion of the helium reservoir, and is cooled by the evaporated gas leaving the helium reservoir.

Radiation effects are further minimized by the use of multi-layers of thin aluminized Mylar (called 'superinsulation') which is wrapped over the shields. Typically up to 50 layers of superinsulation are wrapped over the radiation shields. Figure 3 shows a typical cross-section of a cryostat with an integral liquid nitrogen reservoir.

The cryostat cannot completely thermally isolate the helium vessel, and so it is inevitable that small amounts of liquid helium will evaporate. The helium reservoir normally contains enough liquid helium to keep the magnet at least partially immersed in liquid for typically up to a year. Eventually this evaporated helium will need to be replenished. Liquid helium

Figure 3 Cross section of a cryostat with an integral liquid nitrogen reservoir

for refilling is normally supplied in transport Dewars and is transferred to the cryostat using a vacuum-insulated transfer siphon which minimizes the heat load on the helium as it passes through.

Recent developments in cryocooler technology include two-stage refrigerators that achieve temperatures below 4.2 K at the second stage. This allows the possibility of completely stopping the helium boil-off or eliminating the need for liquid helium and relying on conduction cooling of the superconducting windings. These devices rely on special rare-earth compounds in their internal heat-exchanger elements to achieve the low base temperature. Since they do not rely on the expansion of gas through a Joule–Thompson valve, with the consequent danger of blockage by contamination, they promise much improved reliability. Many MRI system manufacturers are now beginning to offer instruments with zero boil-off capability.

In the event of a quench a large volume of gas will be expelled from the cryostat in a short period of time, giving rise to a potential asphyxiation hazard for patients and for personnel operating the system. Unless the magnet is sited in an extremely spacious room it will be necessary to provide exhaust ducting from the cryostat to the outside environment. Gas flow rates during a quench can be very high, and therefore the actual size, length and route of the pipework should be carefully chosen to avoid excessive pressure build up due to flow impedance.

4 FIELD SHIMMING

Although the magnet coils are designed to produce a homogeneous field in the central region of the magnet bore, manufacturing tolerances and effects from external magnetic sources will disturb the homogeneity. Small magnetic fields can be generated to cancel these effects, and this process is called ‘field shimming’.^{6–8} The field is normally shimmed using either small pieces of iron (passive shims), small coils (shim coils), or a combination of both.⁹ Shim coils can be wound from superconducting wire and placed inside the helium vessel. They then operate in a similar way to the magnet. The current in each superconducting shim is set during initial operation, after which the shim power supply can be removed leaving the shim permanently energized at the appropriate current. Alternatively, shim coils can be wound from conventional conductor and operated at room temperature in the warm bore of the magnet. In this configuration the shim coils need to be continuously driven from a suitable high stability power supply.

The variation of the central field of the magnet is usually expressed as a sum of Legendre polynomials and associated Legendre polynomials in a coordinate system in which the origin is at the magnet center. The following equation shows the expansion expressed in spherical coordinates:

$$\hat{H}(r, \theta, \phi) = \sum_{n=0}^{\infty} \sum_{m=0}^n r^n P_n^m(\cos \theta) [A_n^m \cos(m\phi) + B_n^m \sin(m\phi)] \quad (1)$$

where the functions $P_n^m(\cos \theta)$ are known as associated Legendre polynomials; A_n^m and B_n^m are constants which define

Table 1 Cartesian Representation of the Most Commonly Used Shim Channels

Shim	Order, n	Degree, m	Function ^a
z^1	1	0	z
z^2	2	0	$z^2 - 0.5p^2$
z^3	3	0	$z^3 - 1.5p^2z$
z^4	4	0	$z^4 - 3p^2z^2 + 0.375p^4$
x	1	1	x
y	1	1	y
zx	2	1	$3zx$
zy	2	1	$3zy$
$x^2 - y^2$	2	2	$3(x^2 - y^2)$
xy	2	2	$3(2xy)$
z^2x	3	1	$6(z^2 - 0.25p^2)x$
z^2y	3	1	$6(z^2 - 0.25p^2)y$
$z(x^2 - y^2)$	3	2	$15z(x^2 - y^2)$
zxy	3	2	$15z(2xy)$
x^3	3	3	$15(x^3 - 3xy^2)$
y^3	3	3	$15(y^3 - 3yx^2)$

$$^a p^2 = x^2 + y^2$$

the field variation; r , θ , and ϕ are the polar coordinates; and m and n are the polynomial order and degree, respectively.

This is a convenient method of specifying the field variation, as reasonably good approximations to Legendre polynomials can be produced easily with a series of circular arcs. The arcs can then be connected together to form a set of shim coils. A magnet may be supplied with several shim channels, each shim channel being identified by the particular shape of field it produces (defined in the Cartesian coordinate system with the magnet axis defined as the z axis). Table 1 lists the Cartesian representation of the most commonly used shim channels.

During initial installation of a magnet system the variation in the central field is normally mapped by measuring the field strength at selected points in the central field region. The field map can then be analyzed and the required current in each shim channel or the required passive shim distribution calculated.

5 SITING ISSUES AND MAGNETIC SHIELDING

The stray field from an unshielded whole body superconducting magnet will extend far beyond the confines of the room temperature bore. For example, the 0.5 mT contour from a 1.5 T, 1000 mm room temperature bore magnet will typically extend to 11 m on the axis from the magnet center (the earth’s magnetic field is approximately 0.05 mT). Most health and safety guidelines¹⁰ require that people with cardiac pacemakers or other mechanically active implants be excluded from areas in which the magnetic field exceeds 0.5 mT. In regions closer to the magnet where the field exceeds 5 mT ferromagnetic objects start to experience a magnetic force comparable with their weight. In these regions such objects can become extremely dangerous projectiles. In addition to the dangers posed to individuals, certain equipment can be particularly sensitive to magnetic fields. Table 2 gives a guide to the maximum field levels to which various types of equipment should be exposed.

Table 2 Guidelines for the Maximum Field Levels to which Various Equipment should be Exposed

Equipment ^a	Maximum Exposure (mT)
PET scanners	0.1
Nuclear medicine instruments	0.1
CT scanners	0.1
Ultrasound instruments	0.1
Linear accelerators	0.1
Lithotriptors	0.1
Image intensifiers	0.1
Televisions and video monitors	0.1
Computer screens and terminals	0.1
Electron microscopes	0.1
High precision measuring scales	0.1
Cyclotrons	0.1
Cardiac pacemakers	0.5
Neurostimulators	0.5
Biostimulators	0.5
Magnetic media (floppy disks, etc.)	1.0
Video recorders	1.0
X-ray tubes	1.0
Radiography equipment	1.0
Analog watches and clocks	1.0

^aCT, computed tomography.

The fringe field of a magnet system can be reduced either by passive shielding or by active shielding. Passive shielding normally involves the use of mild steel. The steel can be placed within, on, or in close proximity to the cryostat, such that it provides a 'return path' for the magnetic field outside the windings and thereby reduces the overall fringe field. The greater the weight of steel used the greater the shielding effect. Care must be taken to balance the potentially high forces between the magnet and the shield and to ensure that the shield does not disturb the central field homogeneity. Therefore shields placed close to the magnet generally have a high degree

of geometric symmetry. Steel placed more distant from the magnet has less effect on the overall fringe field, but can still provide effective local shielding.

Actively shielded magnets have additional superconducting coils located outside the main coil windings. These extra coils are connected in series with the main coil windings and have their current flow direction reversed. The coil positions and the number of turns are selected to ensure a resultant homogeneous central field region whilst reducing the magnet's fringe field. The advantage of using superconducting coils compared with steel is mainly that the system weight is minimized. Typically 500 kg of superconductor provides the same amount of shielding as 10 000 kg of mild steel. Except for magnets of ultrahigh field strength (greater than 4.0 T), where the technical difficulties are severe, active shielding is usually the preferred method. Figure 4 compares the fringe fields (0.5 mT) from a 0.5 T, 900 mm room temperature bore magnet system in nonshielded and actively shielded configurations.

6 HIGH FIELD SUPERCONDUCTING MAGNET SYSTEMS

Most whole body superconducting magnet systems used for routine clinical MRI operate at field strengths between 0.5 and 2.0 T. However, recent research in areas such as MR spectroscopy, spectroscopic imaging and functional imaging benefit from the improved signal-to-noise ratio and spectral resolution gained from operating at high field strengths (above 2.0 T). Currently, 3.0 and 4.0 T is proving to be a popular field strength for such applications. These systems are now being offered with active screening, which significantly reduces siting problems.

Application-specific 3.0 T systems, with reduced bore size, have recently been introduced, primarily for neuroscanning applications. These systems provide an ultracompact alternative to the whole-body systems. Using NbTi superconductor, whole-body sized magnets with a field strength of up to 10.0 T are theoretically possible. Two ultrahigh field magnets have already been delivered and installed, an 8.0 T, 80 cm bore magnet is being used at Ohio State University and a 7.0 T, 90 cm bore magnet is in use at the University of Minnesota. Magnets at higher fields than these are already in the planning stage.

Ultrahigh field strength magnets have extremely large fringe fields, and therefore siting and shielding issues become very important considerations with such systems. Active screening is technically difficult and iron screens are extremely heavy. Therefore these systems often need to be sited in new buildings where a large area can be reserved for the magnet.

Magnets designed to operate above 10.0 T require part of the coil windings to be constructed from materials other than NbTi. This is because the critical current of NbTi starts to fall very rapidly once the background magnetic field on the superconductor exceeds 10.0 T. Therefore, the innermost windings of the magnet are wound from a material with a higher critical current at these high background field levels. The superconducting material normally chosen is niobium-tin (Nb₃Sn) which has a critical temperature of approximately 18 K. Unfortunately, Nb₃Sn tends to be a very brittle material

**Figure 4** Comparison of the stray fields from an actively shielded and an unshielded 0.5 T, 900 mm bore magnet

Figure 5 An open aspect MR magnet in the Helmholtz pair arrangement

and, as such, is very difficult to handle during manufacture. It is also very expensive compared with NbTi, and therefore magnets which incorporate Nb₃Sn windings tend generally to be limited to small bore analytical NMR magnets.

7 MOBILE SUPERCONDUCTING MAGNET SYSTEMS

A complete imaging facility including a whole body superconducting magnet may be built on a trailer or bus and taken to sites where normally such facilities would not be available. These systems have tended to serve a number of sites within a region. Normally the magnet is energized when the mobile unit arrives on site and is then de-energized before moving to a new location. The magnets used in mobile applications generally have the ability to be ramped rapidly to field and then shimmed automatically. It is typical for the magnet to be ready for MR use within 1 hour of arriving at a site.

8 NOVEL MAGNET GEOMETRIES

Even today's relatively short-bore cylindrical geometry magnets can present problems of claustrophobia for some patients. It is also desirable for the clinician to have good access to the patient, both to reassure them and to be able to perform simple clinical procedures such as insertion of catheters during imaging. These requirements have led to the development of MR magnets with 'open access'.

One example of an open-aspect MR magnet is the Helmholtz pair arrangement (shown in figure 5) whereby two cryostats are positioned opposite each other with an intervening gap. The intervening gap allows an attendant or even a surgeon to have access to the patient during the imaging process. There needs to be connection between the two cryostats in which to feed magnet wires and to allow cooling to be shared between the halves. A particular design challenge for this type of magnet is to contain the relatively high attractive forces between

the halves with a minimally obtrusive structure. Some versions of this format are actively screened; currently 0.5 T is the highest field strength offered.

Another example of an open-access cryogenic magnet is the 'super-C'. This consists of a pair of superconducting driver coils with an iron structure forming pole pieces and a return flux path. A variety of formats have become available using superconducting drivers with iron structures to produce a homogeneous field region. Some have pole gaps in the horizontal direction, others in the vertical direction.

1 INTRODUCTION

The motivation for investigating the use of internal coils in MRI and MRS is based on the fact that the closer an MR signal detector is placed to its target the better the signal-to-noise ratio (SNR) of the resultant data. Abragam described the significance of the 'filling factor' of an object in a coil¹ and Hoult and Richards developed the theory of the SNR of the MR experiment round this concept.² SNR is maximized if the coil size is matched to that of the region of interest; coils located very close to the target to be studied can achieve dramatic improvements in SNR relative to conventional external enveloping coils. Internal access for such small local coils may be gained via natural orifices or using other minimally invasive techniques.

In the first part of this article the design and construction of the current range of internal coils used for human MRI is reviewed. Discussion of types that are in development and which may become of clinical relevance in the next few years follows, including descriptions of their clinical use where relevant. The second section describes the main clinical applications to date. Development has been gathering pace during the 1990s, and it is expected that within the next few years the variety of devices will increase substantially.

1.1 Historical Note

The first implanted or inserted coils to be described were intended for spectroscopic investigations.^{3,4} These were followed by initial studies of devices for MRI.^{5,6} The first clinical studies using an inflatable rectal probe (Medrad Inc., Pittsburgh, USA) were published in 1989.⁷ Various studies were undertaken with this probe (e.g., that of Schnall *et al.*⁸), but it was not until 1992 that other designs began to appear. The first of these was a coil designed for the imaging of the cervix,⁹ this was followed by probes for the anus^{10,11} and an alternative design for the rectum.¹² Other coils were used in conjunction with endoscopes, principally for gastroscopy,^{13,14} and smaller versions were designed for such applications as imaging the inner ear¹⁵, and the female urethra.¹⁶

All these devices are designed for insertion through natural orifices to acquire imaging (or in some instances, spectroscopic) data from adjacent regions of interest. Another class of detector acts as markers. An early design used a small coil to mark the tip of a catheter.¹⁷ Later versions of this concept were designed to generate signals along significant lengths of conductor, mimicking a guidewire. These included stub aerials^{18,19} and extended coil windings.²⁰ Of these, the aerial version gives a wider field of view and may eventually prove useful for local imaging.¹⁹ We have used the same approach to mark the location of a naso-gastric tube (unpublished data), and it is likely that other clinical applications will develop over the next few years. A specialist application is in the development of marker (fiducial) technology, which provides a spatial reference point. Fiducials can be passive (as developed primarily for frameless stereotaxy²¹) or active, in which rf circuitry is used to enhance or characterize signals. The latter typically use tiny vials of an MR-visible material enclosed within the windings of a very small coil.²² Fiducial markers may also be integrated into internal coils or biopsy devices in order to track their trajectories.²³

2 DESIGN CONSIDERATIONS

2.1 General Features

Insertable coils may be designed for use in one of three ways: (i) as an enveloping coil with the principal target for study being tissue within the coil (the cervical coil described here uses this strategy); (ii) as an 'inside-out' coil in which a winding design normally used in MRI to produce images from the volume enclosed within it is used to obtain data from outside it (e.g., the endoanal coil); (iii) as a coil used in a manner analogous to that of a conventional surface coil (e.g., the endorectal coil).

Insertable coils can be used as receivers only (either single or in arrays) or as combined transmit/receivers. In general, the coils are directly coupled to the input receiver via a cable. However, in certain specific applications (e.g., endoscopic) the coil may be inductively coupled to the external receiver.

Coil size is limited by the size of the orifice through which it is inserted and by other structures en route to its intended location. The useful field-of-view of the coil is a function of its dimensions. Typically, for a saddle coil in which the winding width is a quarter of its length, sensitivity drops to about one third of that at the coil surface at a distance equal to the diameter of the former on which it is wound. While it is arguable as to what is acceptable from a SNR point of view, a rule of thumb is that the useful field-of-view of a coil is approximately equal to twice the winding width.

Patient safety is a key requirement. In most instances, electrical connections have to be made to the outside world and there are potential risks from conductors behaving as aerials, or from the formation of conducting loops. Insulation of conductors and biocompatibility of constructional materials are, therefore, important. A further complication is the sterilization of devices. Unless the devices are cheap enough to be discarded, consideration of the requirements for cleaning and sterilization for re-use is necessary. In order to avoid motion artefact degrading imaging quality, the coil also needs to be

immobilized relative to both the machine measurement frame and the tissue surrounding it during data acquisition.

2.2 Transmit/Receive Operation

In typical MRI studies where spatial encoding is used with the coil in receive mode, voxels are smaller than the coil dimensions and coherence of signal phase is preserved within each voxel. The SNR is much lower in spectroscopic data acquisitions than in imaging studies, and the voxel size is correspondingly larger. The filling factor gains in SNR associated with MRI do not then apply. This is because the rapid changes in flux direction relative to the small coil result in partial signal cancellation if the whole volume round the coil is excited uniformly by an external transmitter (Figure 1) and there is a subsequent reduction in the net SNR in the large voxel studied. A transmit/receive coil avoids this signal loss because the phase and magnitude of the transmit field mirrors the flux pattern in the receive mode.

Internal transmit/receive coils may also be used for imaging in cases where the volume of excitation must be restricted. This has proved useful in the case of the twisted pair guidewire tracking device and in the cervical coil where rf irradiation to a pregnant uterus may be undesirable.

Figure 1 The effect on signal of the voxel size relative to coil size. In a voxel large enough to envelop flux in opposing directions (A), spins in regions of opposing flux cancel each other and reduce the net signal. In a small voxel (B), the flux is unidirectional and all the spins contribute to the net signal. If, however, the coil is used to transmit as well as receive, the flux reversal applies in both transmit and receive modes even in a large voxel and all the spins contribute to the net signal

2.3 Tuning, Matching, and Decoupling

Solenoidal magnets commonly operate between proton resonant frequencies of 21 and 65 MHz, while magnets with transaxial fields currently have proton resonant frequencies in the range of 8.1–25 MHz. Since the windings are constrained to be similar at all fields for any one class of coil, and are of low inductance, all rely on substantial tuning capacitors mounted close to the imaging field-of-view for good performance. The requirement for small components with minimal ferromagnetic content is an important consideration particularly for capacitors.

Figure 2 shows the tuning, matching, and decoupling circuitry for the endorectal array described by Gilderdale *et al.*²⁴ This circuitry is designed for receive-only operation and includes the components needed for active decoupling of rf transmitter pulses. The component values, and circuit detail, are those for operation at 0.5 T (21.3 MHz) in a solenoidal magnet. Active decoupling is used to ensure that the coupling between the receiver coil and the transmit field is eliminated and is independent of the time-dependent rf B_1 fields, levels, though it does require that suitable control lines are available from the machine being used.

2.4 Direct or Inductive Coupling

The elimination of cable connections to internal coils is very attractive in some circumstances; for example, if there is reason to implant a detector (in the same way as a pacemaker) and leave it in position while the patient continues with other activities between repetitive scans. The approach is also potentially valuable in circumstances where there may be technical difficulties in making connections, where there are safety issues if direct coupling is used, and where cabling becomes an embarrassment (either because of the number or the extent of the cables).^{4,22,25}

Normally the external and internal coils are loosely coupled, since the latter are typically at a distance from the former. The external coils are several times larger in dimension than the internal coils; reciprocity means that the system is generally applicable to reception of signals as well as transmission. Figure 3 is an illustration of the technique used with a small fiducial coil, used either as a position marker or to track motion. The small coil can act as a flux amplifier which enables a 90° flip angle to be achieved within the marker sample while the magnetization of the surrounding tissue experiences negligible disturbance. This allows motion tracking to be interleaved with image data acquisition without the latter being compromised.

2.5 Orientation of Coils Relative to the Main Field

Certain coil designs (e.g., enveloping solenoid used for imaging the uterine cervix) give near optimal performance because anatomic features allow them to be orientated perpendicularly to the fixed magnetic flux density field B_0 . However, in situations where the orientation is not fixed (e.g., in endoscopic applications) significant improvements in SNR of internal coils and implanted devices can be achieved with a quadrature design. At least one of the two quadrature windings must be orthogonal to the main field and so capable of detecting excited

Figure 2 Circuitry associated with the endorectal array

signals. Three orthogonal windings, though increasingly hard to implement in a small unit, ensure signal detection at all times.

Because of anatomic considerations for coil insertion, the formers are often cylindrical. This implies that windings are either short solenoids or saddles. Variants of these designs were the basis of most external receiver coils employed in early MRI systems using cryogenic magnets.²⁶

2.6 Artefacts

The sensitivity profile of a small internal coil results in very high signal adjacent to the coil surface and obscures image detail in this region. In general, a correction algorithm needs to be applied to the images to optimize their interpretation. In some applications it is possible to use the known sensitivity profile of the receiver coil to generate the correction.

As with conventional external coils, loss of signal occurs wherever the flux lines are parallel to the B_0 field. If this happens within the imaging region of interest it can cause 'blind spot' artefacts. This is of particular relevance in endoscopic applications and can be counteracted by the use of quadrature designs (cf. Section 2.5).

Figure 3 Coupling of a small inserted or implanted coil and a large external one. The shaded volume is a small vial of an appropriate NMR signal-generating material around which is wound a small tuned coil of inductance L_2 and resistance R_2 , which is tuned to the system resonance frequency by a capacity C_2 . The large coil, which is connected to the scanner, has respective tuning parameters L_1 , R_1 , and C_1 . Its quality factor (Q , reflecting the efficiency of the system), is given by $\omega L_1/R_1$, where ω is frequency

The most pernicious artefact encountered with internal coils is caused by motion, in which the coils move relative to the tissues of interest. Even when the coil is apparently firmly situated within the body, any patient motion can re-orientate the coil relative to the target source of signals. In endoscopic applications where the coil is located at, or ahead of, the tip of a flexible endoscope, the coil is liable to uncontrollable small movements. Reduction of motion artefact can be accomplished using fast imaging techniques; however, these not only suffer from a lack of robustness but also the small fields-of-view and thin slices used with internal coils make enormous demands on the machine gradients. Other well-established methods for motion artefact control use navigator echoes and phase-encode reordering, but again with the restricted field-of-view from the internal receiver, anatomic landmarks are difficult to identify clearly. Currently we are investigating the use of fiducial markers attached to the imaging coil former to generate reference signals that permit correction of the incoming data.²⁷

Motion artefact can also be controlled by providing a firm anchor in the form of a clamp for the coils wherever possible. The unit shown in Figure 4 is suitable for clamping coils for use in the pelvis. The whole assembly is made from Delrin, with the baseplate being underneath the patient's thighs and so being held in position by their weight. The double bosshead arrangement allows sufficient flexibility in orientation for a range of coils, and the whole unit is simple to clean.

3 IMAGING TECHNIQUE

Imaging techniques at 0.5 T (Asset) or at 1.0 T (HPQ Vista, Picker International, Highland Heights, OH) include T_1 -weighted spin echo [repetition time (TR) range 720–820 ms; echo time (TE) 20 ms], T_2 -weighted spin echo (TR 2500 ms; TE 80 ms), and fast spin echo (TR 4500 ms; TE 96 ms) sequences. Transverse and sagittal 3.5 mm contiguous slices obtained with a 192×256 matrix, two to four signal averages, and a 10–12 cm field-of-view, provide optimal resolution while maintaining the SNR. In addition, a short inversion time (107 ms at 0.5 T) inversion recovery sequence (STIR) (TR 2500 ms; TE 30 ms) provides robust fat suppression and enables delineation of lesions with long T_2 times, for example fluid collections and tumors.

Figure 4 A clamp used to immobilize coils. For pelvic applications, the baseplate is placed under the patient's thighs. The double bosshead provides sufficient adjustment to cope with variations for the different coils and for individual patient requirements

4 CONSTRUCTION AND APPLICATION OF TYPICAL COILS

Coil formers are made of an acetyl homopolymer (Delrin), as this is mechanically easy to handle and machine, has good rf properties, and is a nontoxic, biocompatible material that meets sterilization requirements. Delrin is water resistant and retains its shape despite repeated soaking in noxious sterilization fluids. The coils are wound from solid copper wire and are coated with an epoxy resin that is water resistant, biocompatible, and provides a seal for the electronics. In our experience, a typical coil has lasted for several hundred patient examinations without requiring renewal. The following sections describe the range of coils that we have developed and indicate what may be possible as capabilities expand.

4.1 Cervical Coils

Intravaginal enveloping cervical coils have been designed for use at 0.5, 1.0, and 1.5 T to operate in receive mode. A range of coil diameters has been investigated, 37 mm being a good compromise between accommodation of the cervix and ease of insertion. The coil is mounted on a cylindrical Delrin former attached to a 20 cm long Delrin handle (Figure 5a).

The anatomy of the uterine cervix provides a rare opportunity to exploit the superior SNR performance of a solenoid coil in a conventional MR scanner where B_0 is parallel to the long axis of the patient. Although the use of a coil in the vagina to image the cervix has been described by others,²⁸ the coils used had a simple loop geometry. The use of an enveloping cervical ring provides the best resolution of the cervix and the adjacent parametrium; with good positioning, such a coil provides a uniform signal from the structure it encircles. The coil is easy to position following digital examination, particularly in the ante-

verted uterus. However, even in retroverted uteri, a speculum examination is unnecessary. Although artefacts may obscure a few millimetres of the surrounding vaginal vault because of the proximity of the coil, these artefacts cause no problems in diagnostic accuracy. Also, the coil assists with interpretation by distending the vaginal vault and separating the vaginal wall and cervix.

4.1.1 Normal Anatomy

Both T_1 - and T_2 -weighted images show the normal cervix to consist of two distinct stromal zones and the mucosa surrounding the central canal.²⁹ The mucosa has a relatively high signal on both T_1 - and T_2 -weighted images. Mucosal detail can be appreciated with this technique (pixel size 0.6 mm) (Figure 6). It shows a smooth and regular outline in the nulliparous cervix and a more irregular and indented outline in the parous cervix. In addition, dilated glands filled with secretions are sometimes seen in the latter.

On administration of 0.1 mmol kg⁻¹ body weight gadopentate dimeglumine, brisk mucosal enhancement begins at 30 s after injection and peaks at 120 s. The fibromuscular stroma enhances more slowly, with the outer ring showing more prominent enhancement, making zonal differentiation maximum at 90 s.

4.1.2 Cervical Cancer

There is good agreement between the high-resolution MRI findings obtained with an endovaginal coil and the pathological findings in patients with clinical evidence of stage I cervical cancer.³⁰ With standard body coil images, it is often difficult to assess the integrity of the stromal ring (Figure 7). The cervical coil makes such assessments easier, which has been confirmed by comparison with histology.³⁰

Figure 5 Coils for internal use. (a) Cervical coil; (b) cylindrical anal coil; (c) solid endorectal coil; (d) coil for use with a gastroscope or colonoscope

Parametrial invasion may be recognized when there is loss of the low-signal-intensity stripe of normal stroma of the cervix together with diffuse or localized abnormal signal intensity within the parametrial region. Parametrial tumor spread may be

overestimated because of peritumoral inflammatory tissue, which is well known as a cause of tumor overstaging.³⁰ With carcinoma of the cervix, intravenous contrast agents are of limited value,³¹ although dynamic contrast enhancement has been

Figure 6 Images of the normal cervix using T_2 -weighted spin echo (repetition time 2500 ms; echo time 80 ms) images through the cervix in (a) transverse and (b) sagittal planes. The coil is seen as an outer ring of signal void (black and white arrows). The mucosal layer is irregular (small straight arrow). There is an inner zone of low signal intensity (curved arrow) that corresponds to a highly cellular layer and an outer intermediate signal intensity zone (large arrow) that is less cellular

Figure 7 Images of Stage Ib squamous carcinoma of the cervix. Sagittal T_2 -weighted spin echo (repetition time 2500 ms; echo time 80 ms) images through the cervix using (a) a cervical coil and (b) a phased array coil. The small tumor with intermediate signal intensity (arrows) is seen in both instances. However the margins are clearly defined in (a) and are difficult to differentiate in (b). There is no extension to parametrium or vagina. This was confirmed on the histology of the radical hysterectomy specimen. A, anterior; P, posterior

reported to be valuable in the accurate assessment of cervical invasion by tumor.³² We used dynamic contrast-enhanced imaging in three slice positions over a 5 min period, though in no case did these images provide information not available on T_2 -weighted images.

High-resolution images of the cervix are particularly important in defining tumors that are less than 1 cm³ in volume because the definition of their extent has a significant impact on clinical decision making.³³ High-resolution images also may guide the approach to the histologic dissection of the resected tumor and thus not only optimize the surgical approach but also facilitate longer-term management.

4.2 Anal and Urethral Coils

Anal and urethral coils are simple saddle windings when implemented for solenoidal magnets. A variety of coil sizes have been developed for use at different field strengths and for different applications. Cylindrical endoanal coils have diameters ranging from 9 to 12 mm, and lengths of 75–100 mm: the largest version is shown in Figure 5b. Variants of the basic design include arrays and the integration of a pair of fiducial coils.

A wide variety of pathology in adults and children has been imaged using these coils, including infection, trauma, tumors and congenital malformations of the anal sphincter.^{33–38} The superior image resolution allows identification of small fistulae-in-ano, assesses muscle defects, and defines the extent of tumors.

4.2.1 Normal Anatomy

From medial to lateral, several layers are recognized. A layer of mucosa with high signal is surrounded by a region of submucosa and subepithelial muscle (musculus submucosae ani) with low signal. The abundance of collagen and elastic tissue probably accounts for the short T_2 time of this region (Figure 8). The internal sphincter is distinguished by its high signal intensity on all sequences and often appears crescentic, being thicker anteriorly. The characteristic high signal appearance of the internal sphincter is not merely a result of its closeness to the coil; persistence of this high signal pattern on correction with a signal intensity profile from phantom data suggests that it is intrinsic to the smooth muscle of the internal sphincter. Its presence *in vitro* also suggests that it is not a consequence of the normal resting tone of the internal sphincter.³⁸ The intersphincteric region has a high signal on T_1 - and T_2 -weighted spin echo images: this is nulled on the STIR images, which is consistent with the presence of fat. The conjoined longitudinal muscle and external sphincter have a low signal intensity (Figure 8). The oblique coronal plane is particularly useful in demonstrating the three components of the external sphincter (subcutaneous, superficial, and deep) (Figure 8) and their relation to the levator ani.

Like the model described by Oh and Kark,³⁹ the female anal sphincter is shorter anteriorly than posteriorly. Inferiorly, the anterior margin of the superficial and deep external sphincter are continuous with and inseparable from the perineal body (Figure 8b). The transverse perineal muscle bridges the inferior part of the external sphincter anteriorly (Figure 8c). Superiorly,

Figure 8 Normal anal anatomy in a 44-year-old female. Spin echo T_1 -weighted [repetition time (TR) 720 ms; echo time (TE) 20 ms] images in (a) coronal and (b) transverse planes; (c) spin echo transverse T_2 -weighted image (TR 2500 ms; TE 80 ms); (d) STIR (short inversion time inversion recovery; inversion time 107 ms; TR 2500 ms; TE 30 ms) images at a mid-sphincteric level in two planes. The coil is seen as a central signal void. The mucosa (black and white head) gives a very high signal on all sequences. The submucosa (small white arrow) is low signal. The internal sphincter is a homogeneous band (curved arrow) and has a particularly high signal in (c) and (d). The external sphincter is relatively low signal on all sequences. In (a) it is seen in its three components, subcutaneous (lower broad arrowhead), superficial (short black arrows), and deep (long black arrow)

perineal glands directly about the internal sphincter anteriorly and laterally, separating it from the muscle of the vaginal wall.

4.2.2 Perianal Sepsis

The change in T_1 and T_2 times associated with infection produces high soft tissue contrast and enables abscesses and fistulous tracks to be demonstrated. Although previous studies using a conventional body coil have detailed the efficacy of MRI in demonstrating fistulae⁴⁰ and changes in Crohn's disease,⁴¹ the excellent image quality provided by an internal coil results in further improvement. With more traditional anal endosonographic techniques,⁴² tissue contrast is less good, the technique is more operator dependent, and it is no more accurate than digital examination under general anesthesia.⁴³ With endoanal imaging, in simple as well as in complex fistulae, it is relatively easy to identify a collection and define its extent (Figure 9b) as well as to follow the primary tracks in multiple planes to find the site of the internal fistula opening.

The position and course of the track in relation to the anal verge and the levator ani can be documented from the coronal and sagittal images. The resolution of the technique (pixel size 0.6 mm×0.6 mm) ensures that even small collections of the order of a few millimeters can be identified. Surgical management critically depends on the detection of these small collections, the site of the primary track, and the position of the internal opening.

4.2.3 Fecal Incontinence from Surgical Trauma

Perineal surgery may inadvertently cause a breach of the external or internal sphincter. The external sphincter is particularly at risk during procedures such as hemorrhoidectomy, vulvectomy, and colposuspension. The internal sphincter is particularly vulnerable in lateral sphincterotomies for chronic anal fissure when complete division of the internal sphincter may result in fecal leakage.

4.2.4 Fecal Incontinence from Obstetric Trauma

Early-onset fecal incontinence Fecal soiling immediately following childbirth is a dramatic symptom and, because intact sphincter musculature is essential to maintain continence, this suggests that part of the external sphincter has been ruptured. Defects in both internal and/or external sphincter are usually strikingly apparent on endoanal MRI. Tears involving the internal sphincter are immediately recognized because of the profound loss of the high signal intensity normally seen in this homogeneous muscle ring. In patients with rectovaginal fistulae, long T_2 tracks are seen to course anteriorly between anus and vagina.

Although endoanal sonography can provide anatomic information, particularly of internal sphincter damage in obstetric trauma,⁴⁴ it poorly defines the echogenic external sphincter against the echogenic perianal fat. Endoanal MRI not only

Figure 9 Images of the anal sphincter in anal sepsis using a 12 mm, endoanal coil; (a) transverse T_2 -weighted spin echo [repetition time (TR) 2500 ms; echo time (TE) 80 ms]; (b) coronal short inversion time inversion recovery (STIR) (inversion time 107 ms; TR 2500 ms; TE 30 ms). The endoanal coil appears as a central signal void. An extrasphincteric collection is seen at 3 o'clock in (a) (arrow); however, there is no extension above the levators in (b) (arrows)

shows internal sphincter damage but also accurately delineates how much of the external sphincter has been disrupted.

Late-onset fecal incontinence In patients presenting with fecal incontinence starting several years after childbirth, a different pattern of sphincter abnormality is seen. The internal sphincter is relatively normal in thickness, but marked atrophy of the superficial and deep components of the external sphincter is evident (Figure 10). The subepithelial muscle is thicker in the fecally incontinent group compared with that in age-matched normal controls,³⁸ probably because of compensatory hypertrophy.

4.2.5 Fecal Incontinence in Systemic Conditions

Patients with scleroderma and fecal incontinence show a striking abnormality of the anterior sphincter musculature. There is buckling forward of the anterior rectal wall and anal sphincter musculature, with descent of rectal air and feces below the levators into the upper half of the anal canal.⁴⁵ There is also a significant reduction in internal anal sphincter bulk compared with age-matched fecally incontinent subjects who do not have scleroderma.⁴⁵ Patients with scleroderma but without fecal incontinence sometimes show these features.

4.2.6 Tumor

In patients with low carcinoma of the rectum, the extent of tumor invasion of the sphincter can be delineated with endo-

anal MRI.³⁶ Irregular lobulated masses of high signal intensity may be seen (Figure 11) on T_2 -weighted sequences, which allow visualization of tumor invasion and breakthrough of the muscular coat of the anorectum. If lack of anal invasion is confirmed on endoanal MRI patients may be offered an anterior resection.

The multiplanar facility of MRI allows clear delineation of tumor extent and invasion particularly in relation to the levator floor. The exact distance from each of the components of the external sphincter and the extent of internal sphincter involvement can be accurately asserted prior to surgical planning.

4.2.7 Congenital Anorectal Anomalies

Smaller diameter (7 and 9 mm) coils are used for defining sphincter abnormalities in children with anorectal anomalies. The sensitive region of the various diameters of coil is chosen to suit the dimensions of the anal sphincter in the various age groups. The technique delineates the thickness and position of the muscle components as well as the presence of fistulae with neighboring structures (Figure 12).

The use of an anal coil causes minor discomfort but is acceptable and well tolerated in unsedated children of more than 8 years of age and appears to be better tolerated than digital examination. Children aged less than 8 years normally require sedation for an MRI scan even with an external coil.

Figure 10 Sphincter atrophy in a patient with long-standing fecal incontinence following childbirth. Spin echo images (repetition time 720 ms; echo time 20 ms) T_1 -weighted in (a) transverse and (b) coronal planes. Following traumatic childbirth several years earlier, there is focal atrophy of the internal sphincter (small arrow) in this patient and more global atrophy of the external sphincter (large arrow)

Figure 11 Squamous cell carcinoma of the anus. Transverse T_1 -weighted spin echo image (repetition time 660 ms; echo time 20 ms) showing an intermediate signal lump (arrows) in the right anterior quadrant between 9 and 12 o'clock involving the subcutaneous external sphincter

Figure 12 Perineal fistula in an 18-month-old girl. Sagittal T_1 -weighted spin echo image (repetition time 720 ms; echo time 20 ms) through the mid-sphincter (a, anterior, p, posterior). The 7 mm coil is seen as a central signal void. There is generally good sphincter bulk. A high signal track is seen to extend anteriorly (arrow). It communicates with an opening in the posterior vaginal fourchette that was seen to discharge feces

4.3 Endorectal Coils

The balloon type of endorectal coil was the first internal coil to be developed.⁵ We developed a similar version of our own to operate at 0.5 T as coils for that field strength were not available commercially. Subsequently, a smaller rigid device was developed which both operators and patients preferred,¹² and this device is described here.

This coil (Figure 5c) is essentially a surface coil designed to be placed in the rectum posterior to the prostate gland, and consists of an $8.5\text{ cm} \times 2.5\text{ cm}$ semicylindrical former. The flat upper surface is used as the base for the $6.5\text{ cm} \times 2.5\text{ cm}$ winding. This solid, one-piece surface coil is placed in the rectum. The tip of the coil is tapered and it is easy to insert and position following standard digital rectal examination in the lateral decubitus position.¹² Our solid one-piece endorectal coil is easy to handle and set-up, is re-usable, and does not require external tuning and matching. Also, unlike the commercially available coil, there are no artefacts from susceptibility effects of the air in the balloon, which degrade the prostatic images. The solid design also allows incorporation of a needle guide, and with further refinements will enable MR-guided transrectal biopsy.

4.3.1 Normal Anatomy

The zonal anatomy of the prostate may be identified clearly on the high-resolution T_2 -weighted images obtained using the endorectal coil. The outer homogeneous zone of high signal intensity (peripheral zone) forms the bulk of the gland in young males. The inner zone (central zone), which histologically comprises the 'transitional' lobe of the prostate, increases in size with age and displaces the peripheral zone laterally.

4.3.2 Benign Prostatic Hypertrophy

In benign prostatic hypertrophy, the enlarged central zone of the prostate forms a nodular, inhomogeneous adenoma that often includes cystic nodules and calcification. With increase in size it commonly causes compression of the prostatic urethra and leads to bladder outflow obstruction. This normally requires intervention with conventional surgery or minimally invasive thermal ablative techniques. In the latter instances, intraoperative image guidance is becoming increasingly popular. We have demonstrated that intraoperative changes seen on endorectal imaging may be used to predict more long-term outcome;⁴⁶ the development of a periurethral band of low signal at the time of surgery correlated with a significant reduction in symptoms at 3-month follow-up (Figure 13).

4.3.3 Prostate Cancer

Endorectal imaging is routinely used in the detection of prostate cancer (Figure 14). Malignant nodules are usually recognized as low-signal foci within the peripheral lobes: however, they are sometimes iso- or even hyperintense compared with background and, therefore, are difficult to detect. Also the multifocal nature of this disease means that small malignant foci may go unrecognized. Recently, dynamic contrast-enhanced techniques have been used to map out the full site and extent of malignant foci,⁴⁷ and this approach may be adopted to monitor the response to medical therapy.

Figure 13 Appearances after endoscopic laser prostatectomy for benign hypertrophy. Transverse T_2 -weighted spin echo images (repetition time 2500 ms; echo time 80 ms) before (a) and immediate after (b) a four-quadrant ablation of the prostate using a noncontact laser. (a) The small central adenoma (arrow) was causing significant symptoms. (b) There is overall swelling of the gland with loss of the normal zonal differentiation. A periurethral ring of low signal is seen (curved arrow) that is likely to represent coagulative necrosis

Figure 14 Prostate carcinoma with extracapsular extension. Transverse T_2 -weighted spin echo image (repetition time 2500 ms; echo time 80 ms) through the mid-prostate. A large mass is seen on the right that extends into the periprostatic tissues (curved arrows)

4.4 Endoscopic Coils

A gastroscope and colonoscope coil design is shown in Figure 5d for comparison (see *Gastroscopy and Colonoscopy*). This uses a Delrin former with a saddle winding and connecting cable. The coil unit is located ahead of an MR-compatible gastroscope or colonoscope and the cable is passed through the 3 mm channel usually allocated for biopsy devices.

4.5 Miscellaneous Coils

Use of small coils in the external auditory meatus, within blood vessels, and for dental applications have been investigated. The problems with such coils include achieving a useful field-of-view from something with a diameter small enough to be located around or within the structure being studied.

5 CONCLUDING REMARKS

The use of internal coils allows high-resolution images of the part under study. Improved performance is achieved by superior coupling to the tissue of interest while minimizing coupling to irrelevant regions. A solid design with external immobilization results in re-usable coils without susceptibility artefacts.

Eddy Currents and Their Control

Michael Burl and Ian R. Young

The Robert Steiner MRI Unit, Hammersmith Hospital, London, UK

1 INTRODUCTION

Even in very early imaging systems it became apparent that the pulsed gradient waveforms were being distorted by eddy currents induced in parts of the magnets and other structures. The first machines were resistive, and the coil formers were the main source of trouble. These could be split, which helped to some degree, but the problems were even more severe in the cryogenic magnets introduced later.¹ The use of composition cylinders, instead of aluminum, for their warm bores minimized some problems but, in the end, meant that the structures where the eddy currents circulated were at low temperature with much increased conductivity so that the currents induced persisted for long periods. This article discusses the principal manifestations of eddy currents, and describes the main strategies which are used to combat them.

2 FORMS OF EDDY CURRENT DISTURBANCE AND ANALYSIS

Eddy currents are induced in conducting structures exposed to changing magnetic fields. These currents distribute themselves so as to expel the external field. In superconductors the magnet fields are excluded completely from the material by surface currents. In normal conductors the induced currents give rise to an electric field within the conductor which allows the magnetic field to propagate through the conductor. The finite conductivity of normal conductors results in Joule heating from the induced eddy currents. These effects have been well described by Skilling² and later by Lammerauer and Slapfl.³ In the context of magnetic resonance the eddy currents distort the time domain gradient waveform shape. Furthermore, the distortion may have a spatial dependency.

2.1 Time Domain Analysis

An analytic treatment of the effects of eddy currents is given by Lammerauer and Slapfl³ for the transmission line problem. Although this is a transient solution, giving an answer directly in the time domain, the mathematics needed are apt to be very untidy. A more general and practical solution is to use the finite-difference time domain (FD TD) solution to Maxwell's equations.⁴ This finite element method allows the computer solution of complex metal/dielectric structures, but is expensive in terms of computer resources. Since the frequency components in the gradient waveform are essentially low (>1 MHz) the dielectric effects can be safely ignored and a reduced set of Maxwell's equations may be used.^{5,6}

Table 1 Skin depths (δ in mm) for Various Frequencies and Materials

Frequency (Hz)	Cu $\sigma = 5.8 \times 10^7$	Al $\sigma = 3.54 \times 10^7$	Tissue $\sigma = 0.5$
50	9.44	12.3	112×10^3
1000	2.11	2.75	25×10^3
10 000	0.677	0.87	8×10^3
42×10^6	0.01	0.013	123^a

^aAt frequencies above 50 MHz the high dielectric constant of water has a strong effect on the electromagnetic field.

2.2 Frequency Domain Analysis

The normal analytic treatment⁷ considers the solution of Maxwell's equations for a sinusoidal excitation field. This gives rise to the notion of 'skin depth' δ , which is given, for nonferromagnetic materials by

$$\delta = \sqrt{\frac{2}{\mu_0 \sigma \omega}} \quad (1)$$

The skin depths for different frequencies and materials are given in Table 1.

The current distribution as a function of depth in a thick plate is shown in Figure 1. Although the current distribution follows the solid line the effective resistance is given by the conductivity and the skin depth. The resulting gradient field will be the superposition of the free space gradient field and the various fields resulting from the eddy currents.⁸ The gradient waveform may well have frequency components from a fraction of a hertz up to 10 kHz. The resulting waveform will be the Fourier synthesis of each component modified by the frequency dependent nature of the eddy current.

Some structures in the machine, the rf screen for example, are thin compared with δ and a simple coupled circuit analysis gives a useful insight into and estimate of field distortion and power deposition. Considering Figure 2, we find

Figure 1 Current flow versus depth due to skin effects

Figure 2 Equivalent circuit for eddy current induction into the rf screen (or other identified component)

$$V_1(s) = sL_1 i_1(s) + R_1 i_1(s) + sM i_2(s) \quad (2)$$

$$0 = sM i_1(s) + R_2 i_2(s) + sL_2 i_2(s) \quad (3)$$

Rearranging equation (3) gives

$$i_2(s) = -i_1(s) \frac{sM}{R_2 + sL_2} \quad (4)$$

and then substituting back in equation (2) and dividing by i_1 gives

$$Z_{in}(s) = \frac{V_1(s)}{i_1(s)} = sL_1 + R_1 + \frac{s^2 M^2}{sL_2 + R_2} \quad (5)$$

Putting $s = i\omega$ and rearranging

$$Z_{in} = R_1 + \frac{R_2 \omega^2 m^2}{R_2^2 + \omega^2 L_2^2} + i\omega \left[L_1 - \frac{L_2 \omega^2 m^2}{R_2^2 + \omega^2 L_2^2} \right] \quad (6)$$

This analysis was tested on a model gradient coil, first without rf screen material and then with three types of screen material. The results for copper foil, mesh and plate are summarized in Table 2. The current in the screen is given in equation (4). The resulting field at some point in space will be

$$\begin{aligned} B &= S_1 I_1 + S_2 I_2 \\ &= L_1 \left\{ S_1 - S_2 \frac{sM}{R_2 + sL_2} \right\} \end{aligned} \quad (7)$$

where S_1 is the sensitivity of the field winding and S_2 is the effective sensitivity of the shield. It may be helpful to regard $S_1 - S_2$ as the sensitivity of the field winding in the presence of a superconducting shield and L_2/R_2 as the time constant of the shield. The cutoff frequency for a 35 μm copper screen is about 1–2 kHz although the skin depth δ only becomes equal to the thickness at 4 MHz.

This simple model works over a wide frequency range but can fail when the screen material is thicker than δ . However, good agreement between calculated and measured power deposition is found when the screen resistance takes into account the skin depth. The time response for a thick screen will be different from that of a simple CR or LR circuit due to the frequency dependent nature of skin resistance. For this reason several stages of feedforward compensation would need to be employed to get an accurate approximation.

Some, at least, of the eddy current components induced in very cold structures in superconducting magnets can have a

very long time constant indeed (a ‘field soaking’ effect), so much so that they appear to cause a dc offset, detuning the resonance a little. An additional, quite different, problem arises with magnets where the pole pieces are made wholly or partly of iron. In these, the gradient fields spreading into the poles drive the iron locally round different hysteresis loops. Apart from the energy that is dissipated this results in a local non-linear distortion of the field.

3 CORRECTION STRATEGIES

Correction strategies can be divided into two main types: those which depend on eliminating the fields, or current circulation paths, which are responsible for the induction of, or for supporting, the unwanted currents; and those which try to modify machine operation to compensate for the undesirable effects.

3.1 Correction by Coil Design and Modification

The best known, and most effective, means of restraining fields are the actively shielded gradient coil systems first described in 1986.^{8,9} These are fully described elsewhere (see *Gradient Coil Systems*). An outer set of gradient windings is used to prevent field spreading outside them. Actively shielded gradients typically still allow a leakage of 1% of the flux, so it is usually still necessary to apply other measures to eliminate residual effects.

Though this form of shielding is effective outside the gradient coil assembly it has to be designed to have minimal effects inside the volume of the coil. In this, fabrications such as rf coils and screens must be designed so as to avoid circulating, low-frequency currents. Large areas of conductor should be slit and large value capacitors may be used to bridge gaps in rf circuits introduced to stop low-frequency currents circulating. Both simple coils, such as surface coils (see *Surface and Other Local Coils for In Vivo Studies*), and sophisticated designs, such as birdcages (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*), can include such paths unwittingly. Prevention is illustrated in Figure 3. As shown in Table 2, the design of good rf screens is not a trivial matter.

3.2 Correction by Adjustment of Drive Currents

All the other forms of correction depend on modifying the currents supplied to the gradient coils. As a result they can only be used effectively if the structures in which the eddy currents are induced are concentric with the original coils. This limited their effectiveness in many earlier machines before all the problems associated with the relative eccentricities of parts of magnet structures were appreciated.

Several methods have been used to modify the current profile in the coils. These are described in the next section. One other technique depends on adjusting the data sampling rate to accommodate errors in the gradient field.¹⁰ In this method an NMR probe (see Section 4) is sited at a convenient distance from the center of the machine and its output signal is sampled at a constant rate during the period in which signal is to be recovered while the relevant gradient waveform is applied. If

any gradients were constant during this period, the sampled signals would be acquired at fixed phase intervals.

Then, after demodulation,

$$S(n) = S_0 \exp\left(-\frac{n\Delta t}{T_2} - in\gamma r G_r \Delta t\right) \quad (8)$$

at a distance r from the center along a field gradient G_r , and where Δt is the incremental time interval and $S(n)$ is the value for the n th sample. S_0 is the signal at the start of the sampling window. If the sample size is small enough, the output waveform is a decaying sinusoid of fixed frequency, as long as G is constant. In the presence of a varying gradient the phase increment from one sample to the next varies. As long as the gradient instability is invariant, however, and the signal is

sufficiently oversampled, i.e. $n > N$ where N is the number of samples actually needed, then the values of time increment needed $[\Delta t_r \text{ for } (1 \leq r \leq N)]$ to permit a constant phase increment between each sample can be calculated. This defines a sampling table which will both comply with the Nyquist criterion, and produce consistent data for Fourier reconstruction. This method was used by one group in particular in early experiments,¹⁰ and is particularly useful for early acquisition of data after excitation to form a half-Fourier data set, but fell into disuse until it was necessary to try and extend the periods of data acquisition in echo planar data acquisition¹¹ in particular. Modern practice is to oversample the data as far as possible and then process them, with interpolation, to establish what signals would have been obtained if the data had been sampled correctly though at nonuniform intervals.

Figure 3 Drawing of an enveloping coil showing the large capacitors across the low-frequency blocks in the coil

By far the most common method (apart from the use of shielded gradients—and frequently used in conjunction with these as well) is the use of pre-emphasis (G. N. Holland, private communication, 1984), possibly better known as feed-forward. The circuit configuration typically used to correct for four eddy current terms is sketched in Figure 4. The theoretical relationship for one section of the circuit is

$$H(s) = \frac{A_1 s C}{1 + s C} = \frac{A_1 s}{s + (1/CR)} \quad (9)$$

(continuing to use the notation $s = i\omega$). After some rearrangement, this may be compared with equation (4):

$$I_2(s) = I_1(s) \frac{s(M/L_2)}{s(R_2/L_2)} \quad (10)$$

The transfer function for the whole circuit is:

$$H(s) = \frac{1}{5} \left\{ 1 + \frac{A_a s}{s + \frac{1}{C_a R_a}} + \frac{A_b s}{s + \frac{1}{C_b R_b}} + \dots \right\} \quad (11)$$

Figure 4 Schematic circuit design of a four-term pre-emphasis eddy current correcting circuit

Figure 5 Design showing the introduction of a profile correction into a current demand waveform: (a) desired waveform; (b) actual waveform as monitored by probe (before any correction); (c) difference between measured and desired waveform; (d) predistorted gradient drive waveform

Equation (11) may be compared with equation (7). The resistances R_a to R_d are adjusted for each section time constant, and A_a to A_d are adjusted for each section gain factor. The gain factor of $\frac{1}{5}$ is adjusted by further amplification.

Pre-emphasis is a much used and convenient strategy because, if properly implemented, it means sequence designers can ignore the consequences of the pulse patterns they create, and, in principle, any sequence can be run on any machine. The other strategies which depend on the modification of the current pattern to the coils do not have this advantage, but have to be set up sequence by sequence, machine by machine. In these systems the actual gradient profiles are modified so that the demands fed to the amplifiers include correction components for adjusting the current so that it includes a component offsetting the effects of the eddy currents. This technique avoids the problem with the pre-emphasis system of having to decompose all the eddy current components to allow their relatively simple adjustment.

The process can be automated as shown in Figure 5 (D. J. Bryant and G. A. Coutts, private communication 1994). In this approach the iteration starts with the basic desired gradient (a) and the field generated is monitored by a probe (b). The difference between the desired and measured gradient waveform (c) is an indication of the distortion caused by eddy currents. For the period following a slice select or phase encode gradient this should be zero. This difference can be inverted and added to the original demand waveform as a first correction (d). The first correction will not be perfect due to second-order effects, and the correction process can be repeated as required.

An iterative approach is also used for the adjustment of pre-emphasis circuits. In this case a test gradient waveform is followed by field detection after some delay time T_d (Figure 6). Initially, T_d is set of the order of 1 s and the long time constant

Figure 6 Magnetic resonance probe measurement of eddy current effects

effects are compensated for by adjusting the corresponding parameters in the pre-emphasis circuit. The time delay is progressively reduced and the correspondingly shorter time constant parameters are then adjusted.

4 MEASUREMENT TECHNIQUES

Two prime measuring methods are used to observe the eddy current fields in order to correct them: search coils and NMR probes (see Figure 7). The former [Figure 7(a)] are simple induction loops connected to precision integrators. They work most effectively at middle frequencies (components from 5 to 500 Hz typically) and several coils may be used to measure different ranges of time constants. The NMR probe [Figure 7(b)] is a theoretically better solution, but it may require very substantial signal averaging to give adequate signal-to-noise

Figure 7 (a) Schematic representation of the induction loop and integration approach to waveform monitoring. (b) Schematic representation of the NMR probe approach to eddy current monitoring

ratio. Probes are a well known means of setting and checking the fields of the main magnets, and are usually small spheres filled with doped water. When used for calibrating gradient fields, the dimension of the probe in the direction of the gradient should be less than one voxel. This means that the volume of signal source in the probe may be very limited; hence the need to average. Typical probe dimensions for this application are around $1 \times 1 \times 15$ mm (giving a volume of $15 \mu\text{L}$).

5 CONCLUSIONS

Eddy currents were initially little mentioned, and then treated by those who had worked out how to control them as something to be kept secret, not just for commercial reasons, but also by scientific groups who knew it gave their research a competitive advantage. As a result it is hard to give credit to those who really did develop useful methods of overcoming the problems eddy currents create. However, the problems they represent in whole body spatially localized magnetic resonance cannot be underestimated.

ESR Probes as Field Detectors in MRI

Gösta Ehnholm

Picker Nordstar Inc., Helsinki, Finland

1 INTRODUCTION

ESR methods are potentially attractive for monitoring field levels in NMR in general, and MRI in particular, because of their unique combination of great sensitivity, fast response and high signal-to-noise ratio even with very small samples. Resonance lines of many of the possible candidates for use are very narrow, and so the quality of the signals obtained is also high. Some moieties have multiple lines and can resonate in a mode different from that intended; however, those described here do not suffer from that problem and are consequently easy and reliable to use.

There are two major purposes for which such ESR probes are being developed in MRI. These are to monitor and control the main field (B_0) in, particularly, electromagnets, and to act as markers for the positioning of devices and components used in interventional MRI. The former is an extension of methods that have been in use in NMR for many years, but the latter is something quite new and, as yet, there has been a limited description of it¹ in the scientific literature. After some years in which virtually all attention in MRI was focused on superconducting magnets, the recent increase in low-field open magnets has revived the need for field-control systems. These had become largely anachronistic as superconducting units contain flux-locking loops that are used to protect the region where the good field is located against ambient field disturbances.

ESR techniques and methods are being applied in a variety of ways in MRI, but all suffer from the problem that the resonant frequencies at which they operate are very high (gigahertz in typical MRI fields); consequently, direct use of ESR phenomena is very difficult in whole body systems because of rf deposition. This may not seem directly relevant to the topic under discussion, but it arises because it means that communicating with remote probes (which would be very convenient in many circumstances) using the operating frequency of the device itself becomes difficult.

2 ESR SYSTEMS USED

One advantage of the applications discussed here is that the signal power level needed is low and as a result, solid-state devices can generally be used as linewidth requirements are not excessive. There are a number of materials available that are suitable as the basis of the resonance. The units needed for the two applications noted above need not be similar. Good spatial resolution is needed for the localizer but is largely irrelevant for the field monitor. Additional constraints would be added if it were desired to mount the unit outside the homo-

geneous volume or it was to be located in a region where the field was changing very rapidly.

It is useful here to consider the spatial resolution that is needed for a localizer. If its performance is to be such that it does not contribute significantly to system errors, then it is desirable that it should have a resolution of 100 μm , bearing in mind that several localizers may be used in a single configuration. Factors determining the spatial sensitivity of a localizer are the size of the volume of resonant material, its linewidth, and the magnitude of the gradient fields used to provide a scale with which to detect its location. Field gradients (G) of around 15 m T m^{-1} are typical with lower field machines of the kind normally used for interventional MRI. This implies a field variation of 15 $\mu\text{T mm}^{-1}$ (0.15 G mm^{-1}), which happens to be close to the linewidth of the materials used. For a sample size that is a fraction of a millimeter, this gradient does not widen the resonance line appreciably, which would decrease the signal-to-noise ratio. For the field-tracking system the field sensitivity ΔB can be expressed as the product of noise density S (in units of $\text{T Hz}^{-1/2}$) and the square root of the measuring bandwidth $\Delta f^{1/2}$. Spatial resolution (ΔR) is then given by:

$$\Delta R = \Delta B/G = S\Delta f^{1/2}/G$$

where G is the gradient strength (T m^{-1}). The value of S is proportional to sample volume and that of $\Delta f^{1/2}$ to the inverse of the square root of the measuring time. As the localizer may be used to monitor the positions of thin objects such as needles and catheters, it is very desirable that the volume should be very small.

In principle, there are no size limitations for the field lock, apart from the mechanical convenience of finding a suitable location for a small unit rather than a large one. However, it is usually convenient to mount the unit in a poorer part of the field and thereby avoid obstructing the volume where the patient is located; consequently, small sensor size is an advantage. Sample size should be small enough so that the field gradients in the location used do not broaden the resonance line.

One potential problem, however, is the very high operating frequencies needed for use in magnets with fields of 1.5 T or even higher (typically around 41 GHz and upward). At this time, all the work relevant to this article has been performed at low field (0.23 T), with resonance frequencies of around 6.5 GHz.

3 FIELD LOCK SYSTEM

3.1 Description

The system used so far for field lock applications has been a dielectric resonator (Figure 1a) in the configuration shown in Figure 1b. The resonator is normally located in the lower pole of the iron-yoked 'C-core' magnet, towards its center.

3.2 Use of the Field Lock

Figure 1 illustrates the construction and mode of operation of the dielectric resonator used for field locking. The field modulation, as it sweeps the system through the ESR reson-

Figure 1 (a) The dielectric ESR resonator. 1. Dielectric resonator; 2. ESR sample; 3. probe cover; 4. resonator support; 5. field modulation coil; 6. input and output ESR signal plugs; 7. stripline coupling to dielectric resonator; 8. tuning screw for dielectric resonator resonance frequency. (b) Circuit configuration used with the resonator. The box designated SENS contains the probe depicted in (a) 9. Voltage-controlled oscillator; 10. audio oscillator for field-modulation signal (mod) to field modulation coil and reference to phase-sensitive detector; 11. diode detector for detecting amplitude modulation of ESR signal; 12. band pass filter, centered around audio oscillator frequency; 13. phase-sensitive detector, which forms a signal proportional to the offset of the voltage-controlled oscillator frequency from the ESR resonance frequency. The latter is used to control the former and lock it by means of feedback to ' f_{in} '.

ance frequency, in effect results in an output signal that is the derivative of the resonance line. This goes through zero at resonance so that the gain of the signal chain (which is difficult to control) becomes unimportant when the feedback is applied with sufficient gain.

The output of the system to the scanner is obtained from the voltage-controlled oscillator. This signal has to be mixed down to obtain a difference frequency having a low enough value to be readily tracked by a frequency counter. The noise density (S) of the system has been measured inside a MRI magnet with gradients quiescent to find the noise of the unperturbed probe. The measurement was made during a few hundred seconds and the noise spectrum calculated. The white noise floor is typically $0.1 \text{ nT Hz}^{-1/2}$. In addition to this, a component below approximately 1 Hz was noted. This had a $1/f$ dependence and was believed to be caused by influences from external disturbing fields. The electronics used could only measure the frequency of the voltage-controlled oscillator by counting integral periods. If the measurement time was shorter

than about 0.1 s this would have produced another source of noise, which would increase inversely with measurement time or, in other terms, proportionally with bandwidth. This contribution was equal to 0.04 nT Hz^{-1} .

4 FIDUCIAL SYSTEM

4.1 Description

There are a number of materials that could be used as the sample in an ESR resonator for use as the fiducial. These have been evaluated principally for use at zero field by Duret et al., who published data that led directly to the choice of the quiniolinium-*bis*-tetracyanoquinodimethane radical anion (QTCNQ) as the preferred material.² This is a polycrystalline solid that is relatively easily handled and is chemically stable. In a typical application—a probe to locate the tip of a biopsy needle³—a small lump, about 0.5 mm in diameter, of the material is placed inside a loop or cavity (Figure 2). The signals to and from the loop are connected through a thin semi-rigid coaxial cable to a coupling circuit, which contains a varactor for tuning cable and loop together to the ESR frequency, and means for capacitively coupling the probe to an interconnecting cable. This is connected at the other end to a directional element, such as a circulator, to separate the incoming signal from the outgoing one. The circulator matches the cable so that standing waves are avoided; this makes the system insensitive to the length of the cable which can be several meters long. The probe is used with the same electronics as shown in Figure 1b, though it lacks the coils for modulating the B_0 field. This is taken care of by using a separate coil that is made large enough to surround the whole arrangement and so is not in the way.

There is concern, particularly when higher frequencies are used, that probes located inside patients with connecting cables

Figure 2 The type of configuration used with the QTCNQ ESR probe in applications such as the location of the tip of a biopsy needle (QTCNQ, quiniolinium-*bis*-tetracyanoquinodimethane).

that are taken out of the machine could act as aerials for the B_1 field exciting the NMR resonance. These could result in very high localized current flows, capable of significant regional heating of tissue, particularly near the tip of the probe. It is necessary that insulation round the fiducial system is adequate to ensure that this does not happen in any likely set of circumstances. Because of the high frequency of the ESR excitation, this is easy to accomplish: a cable connection at the probe can be designed that has the needed dielectric insulation for lower frequencies, both at the center and at the outer conductor.

4.2 Use of the Fiducial System

In typical applications of the fiducial system, it is necessary to define the position of the probe in three dimensions. The technique used is analogous to that used by Dumoulin et al. to determine the location of a small coil intended for catheter positioning.⁴ Gradients are applied consecutively in the x , y and z directions. In the study of Ehnholm and Vahala, the gradient pulses were approximately 10 ms in duration.³ The position of the probe can then be automatically computed, knowing the values of the applied gradients and the measured field. From the measurements obtained, the noise level could also be found, which was determined in this study to be about 50 nT RMS. Comparing this to the values that might be expected from the field probe, it is about one order of magnitude bigger than expected. This is probably because of a combination of field disturbances caused by the gradient and/or the field-modulating coils and the fact that the feedback loop has to work very hard in tracking the ESR frequency, which makes it more susceptible to noise. Even so, the value is quite small; consequently, the applied gradients can be very modest and good precision for the localization is still obtained.

5 CONCLUSION

ESR probes have been useful for field monitoring, where they have a combination of speed and precision that cannot

easily be obtained with proton NMR-based detectors. At the same time, they can be used in less homogeneous fields, thanks to the small dimensions of the sample.

For positional probes, the same properties make it possible to achieve a very small design that can be fitted inside objects as small as a biopsy needle. A further advantage is the chemical and physical stability of the material used as the sample in the ESR resonator.

Gradient Coil Systems

Robert Turner

Institute of Neurology, London, UK

1 INTRODUCTION

The effect of static magnetic field gradients on the nuclear magnetic resonance signal has been a subject of research interest since the pioneering work of Gabillard.¹ Many practical uses of NMR require the presence of coils in the bore of the magnet which can generate additional fields of specified spatial variation. These are called 'gradient coils', and improvements in gradient coil design have frequently led the way to major technical developments in NMR spectroscopy and MRI. This article will describe the basic issues relating to gradient coil design, fabrication, and activation with electric current. Fuller descriptions of the NMR techniques to which reference is made will be found elsewhere in the Encyclopedia.

Typically, the magnetic field variations desired consist of linear variations in space of the prevailing, and otherwise homogeneous, static magnetic field $\mathbf{B}_0$, which is commonly taken to define the z direction of the coordinate system used in coil design. Thus three independently driven coils are required which generate fields with constant $G_x = dB_z/dx$, $G_y = dB_z/dy$, and $G_z = dB_z/dz$ respectively, over a usefully large volume of space within the larger magnet supplying $\mathbf{B}_0$. This enables the complete MRI repertoire of slice selection and formation of images of slices of arbitrary orientation. The quantities G_x and G_y are referred to as transverse gradients, and G_z is the longitudinal gradient. Most often $\mathbf{B}_0$ is produced by a solenoid with a cylindrical bore, in which case the gradient coils are generally wound on coaxial cylindrical formers within the bore. Other arrangements are sometimes found, such as the 'transverse geometry' configuration,²⁻⁴ in which the axis of the coil formers is perpendicular to $\mathbf{B}_0$. Normally, windings for G_y are obtained by rotating the pattern for G_x by 90° .

2 USES, DESIRED CHARACTERISTICS, AND LIMITATIONS OF GRADIENT COILS

The use of gradient coils has the greatest practical importance in MRI (magnetic resonance imaging), and arises from consideration of the Larmor equation (q.v.), $\omega = \gamma B$. Here ω is the resonant frequency, γ is the magnetogyric ratio, and B is the magnitude of the magnetic field. If a linear field gradient is applied to an object containing NMR-sensitive nuclear spins, their Larmor frequencies become spatially dependent. Different planes in space are thus labeled with different frequencies, so that frequency analysis of the NMR signal can reveal the relative quantities of nuclear spins along the direction of the field gradient. It was this insight, first perceived by Gabillard,¹ which was put into practical use by Lauterbur⁵ and Mansfield⁶ in their implementation of MRI in the early 1970s. Other important uses of field gradients include their role in the selective

NMR excitation of subvolumes of objects⁷ (such as slices which can subsequently be imaged), labeling of moving spins (allowing magnetic resonance angiography,⁸ quantitation of flow,⁹ and molecular mobility¹⁰), and defining of coherence pathways in multiquantum¹¹ or multinuclear¹² NMR spectra.

Given the crucial role of magnetic field gradients in NMR, a surprisingly small number of workers have made major contributions to their development. Well-established recipes, giving coils with reasonable efficiency but with gradients of poor linearity, were the norm until the mid-1980s.^{13,14} There were few attempts to optimize designs, and little debate in the literature. This came about partly because at that time an MR image took many minutes to acquire, and so gradients did not have to be very large or rapidly switched. Furthermore, MR spectroscopy did not then use gradients at all; localized spectroscopy and spectroscopic imaging were mostly developed after 1985, partly in response to improved hardware.

When it became clear that there was a serious need for better quality gradient coils, a number of improvements were made, the details of which are often unfortunately buried in patents and other less-easily accessible reports. They include (a) the use of distributed-winding coils, (b) the introduction of the stream function for current density, (c) the use of the cylindrical harmonic expansion of the magnetic field variation, (d) minimization methods for power dissipation and inductance, (e) improved fabrication methods, such as printed circuit techniques, and (f) high-current gradient drivers.

These innovations allow greater control over a set of gradient coil performance goals, which includes high current efficiency (defined as the ratio of gradient generated to current drawn), rapid switching time (i.e. low inductance), gradient linearity over a large volume, low power consumption, and minimal eddy-current producing interaction with any other equipment. Some of these requirements are obviously in conflict: for instance, to increase the volume over which the gradient is uniform increases the stored magnetic energy, and hence the inductance, as we shall see.

The inductance and power dissipation of a discrete-wire coil cannot easily be written down in a closed form amenable to analytic optimization procedures. It is much simpler to start with an expression for a continuous current density flowing on the surface of a coil former, which is optimized and then approximated with great accuracy by a distribution of wires. However, many gradient coils are still built using a discrete current path approach from the outset. Such coils often have the advantage of simplicity, though their performance may be poor in other respects. There are clearly established limitations to gradient coil performance. These arise from two sources: the laws of electromagnetism, and the physiological effects on nerves of rapidly switched large magnetic fields.

The smoothness of the variation of the magnetic field, which obeys the Laplace equation, away from current sources, means that any coil wound on a cylindrical former gives fields which are nonzero at greater axial distances than the region over which the linear gradient is desired to be established. Physically, a field gradient established in a given volume has a finite stored energy. Any coil which generates this gradient has a larger stored energy E , since for most coil geometries and all methods of coil winding the magnetic field extends beyond the region over which the field is specified as a linear gradient.

Now E is related to the coil inductance L and the supply current I by the equation

$$E = LI^2/2 \quad (1)$$

and thus a gradient coil has a clearly definable minimum inductance consistent with its specified field performance. For a given gradient current amplifier, with maximum voltage and current outputs $V_{\max}$ and $I_{\max}$, the rise time to maximum current (assuming negligible resistance and capacitance) is simply

$$\tau = LI_{\max}/V_{\max} \quad (2)$$

The inductance is thus normally the major determinant of how fast a coil may be ramped with a given power supply, and hence, for a given specified gradient and power supply, the rise time has a well-defined minimum.

However, because of physiological effects, this minimum may not be attainable. For fast enough risetimes and large enough field strengths, the voltage induced in tissue by a rapidly changing field may stimulate the firing of peripheral nerves to a painful degree.¹⁵ The magnetic field threshold for nerve stimulation in most parts of the human body is on the order of 10 mT if the field is switched in 100 μ s or less. To produce cardiac arrhythmias, rapidly switched fields of two to three orders of magnitude higher are necessary.¹⁶

3 CURRENT AMPLIFIERS FOR GRADIENT COILS

The current efficiency of a gradient coil, as defined earlier, increases linearly with the number of coil turns. However, the inductance increases as the square of the number of coil turns. Thus, since the voltage (required to switch the current rapidly) available in a current amplifier has an inevitable upper limit, there is a major incentive to reduce the number of coil turns as much as possible (short of sacrificing the purity of the gradients produced) and to compensate for the reduced efficiency by using amplifiers capable of generating very large currents. Several amplifier design strategies were introduced between 1985 and 1990. The first was simply to use more Class A linear audio amplifiers, connected in series and/or in parallel to achieve the desired combination of voltage and current output. Typically these amplifiers are rated at 160 V, 100 A. Their chief advantage is the ease of generation of any desired current waveform, though this is offset by the very poor energy efficiency, complexity, and bulk of such systems. Usually they are driven in a 'current-controlled' mode, in which a large voltage (sometimes called 'preemphasis') is available to counteract the back-emf generated in the gradient coil during switching, and hence to obtain the fastest possible slew rate [see equation (2)].

Another solution is to supply a large (typically 350 A), well-regulated dc current, and to control it by chopping it at a high frequency (80 kHz or higher). The mean amplitude of the chopped output can be controlled by altering the mark/space ratio of the chopping. The output is then passed through a low-pass filter to remove ripple. Switching times of 150 μ s for currents of hundreds of amperes can be achieved by this means. Many such current drivers can be arranged in parallel to increase the output further. The advantages are low complexity, compactness, and large current output. However, eradicating all traces of the chopping frequency is not easy.

Perhaps the preferred solution¹⁷ is to use recently developed high power silicon switches (SCRs and MOSFETs), which can handle currents of several hundred amperes and voltages up to 1000 V, in so-called 'stored-energy' devices. Here the required high voltage needed to overcome the back-emf created by the coil inductance is provided by a small ancillary high voltage power supply, charging up a large capacitor which can be switched into the gradient coil circuit when necessary. The large steady current needed between gradient current switches is provided by a simple, well-regulated dc current supply.

4 MEASURES OF GRADIENT COIL PERFORMANCE

A satisfactory measure of coil performance includes coil efficiency, inductance, and gradient homogeneity. If the coil efficiency (gradient/current or field/current, depending on the application) is denoted as η , the inductance as L , and the desired field and the achieved field as B_D and B , respectively, over a volume of interest V , the figure of merit β is given by¹⁸

$$\beta = \frac{\eta^2/L}{\{V^{-1} \int_V d^3r [B(r, \phi, z)/B_D(r, \phi, z) - 1]^2\}^{1/2}} \quad (3)$$

This combines a dimensionless measure of inhomogeneity with a term which is independent of the number of turns of the coil, depending only on the winding configuration and coil radius. For purposes of comparison this radius is set at 1.0 m.

It is worth noting that for constant efficiency and winding configuration, by dimensional arguments, the inductance of a cylindrical gradient coil varies as the fifth power of its radius. This underlies the importance of keeping coils as compact as possible.

5 COILS WITH DISCRETE WINDINGS

The most fundamental equation used in gradient coil design is the Biot-Savart law (1820), which relates the magnetic field $d\mathbf{B}$ at a point in space (Figure 1) to the current element I flowing in a line element $d\mathbf{l}$ at a distance r from the point in question:

Figure 1 Diagram showing definition of variables for the Biot-Savart law

Figure 2 Double-saddle transverse gradient coil with coil spacing for optimal gradient uniformity

$$d\mathbf{B} = \frac{\mu_0 I d\mathbf{i} \times \mathbf{r}}{4\pi r^3} \quad (4)$$

This equation is used to calculate fields produced by discrete-wire coils, whether designed by approximating to an optimized continuous current density, or directly as discussed below. Where conductors of large cross section are used it is inappropriate unless the current distribution within the conductor is known or can be estimated.

The archetypal discrete coil is the well-known Helmholtz pair, which consists of two equal coaxial circular coils spaced by their radius. This particular coil spacing removes the quadratic term from the Taylor expansion of the field as a function of the axial coordinate z , so by symmetry the lowest order term beyond a constant field is z^4 . A field uniform to 5% is obtained within a sphere of roughly half the coil diameter. This trick, removing terms of specific order in the Taylor expansion, is widely employed in the design of coils with discrete paths. It can be performed in a systematic way by using the spherical harmonic expansion.¹⁹

In practice, it is difficult to make a discrete arc coil with sufficient accuracy. Any deviation from the prescribed positions will create lower order terms, since a detailed cancellation is implicit in the design technique. Frequently a single turn at each position is insufficient, and when turns are piled up it is difficult to maintain accuracy of positioning. Furthermore, the performance of the coil off-axis is not guaranteed by this design method.

However, the simplest z gradient designed in this way, the so-called Maxwell pair, consisting of two circular arcs spaced by $\frac{1}{2}a\sqrt{3}$, where a is their radius, with antiparallel currents, has proved so simple to construct and of such high current efficiency that it has remained popular even when z gradient coil designs with better field characteristics have become available. This coil, corrected to fifth order, gives a gradient uniform to 5% within a sphere of radius $0.5a$. The gradient uniformity rapidly worsens beyond this radius. At the origin, the gradient efficiency is

$$\eta = \frac{8.058 \times 10^{-7}}{a^2} \quad (\text{T m}^{-1} \text{A}^{-1}) \quad (5)$$

For transverse gradients, the so-called ‘Golay’^{20–22} or double saddle arrangement of eight 120° circular arcs arranged on a cylinder (Figure 2) has been used extensively. For maximum efficiency the return path, distal, arcs should be placed at positions $2.57a$ from the central plane,²⁰ resulting in a coil which is unwieldy in its length and also of large inductance. For this coil the efficiency is

$$\eta = \frac{9.18 \times 10^{-7}}{a^2} \quad (\text{T m}^{-1} \text{A}^{-1}) \quad (6)$$

Compromise positions, with reduced efficiency, have been derived by many workers.^{22,23} Adding further arcs, of different angular widths and at different axial positions,²⁴ allows more design flexibility, culminating in the designs of Siebold.²⁵ However, the poor off-axis performance of this type of gradient coil (uniform to 5% only within a sphere of radius of $0.6a$) does not permit such coils to benefit from the great improvement in efficiency and risetime to be obtained by using a smaller former.

Other types of discrete element gradient coils rely on straight wires arranged on planes. Simple but effective configurations can be derived by considering the expression²⁶

$$B_z(y, z) = \frac{\mu_0 I}{2\pi} \text{Re} \sum_{n=0}^{\infty} (\xi/r)^n e^{-i(n+1)\phi} \quad (7)$$

where $re^{i\phi} = a + ib$, a and b are the (z, y) coordinates of an infinite wire carrying a current I in the x direction, and $\xi = z + iy$. This series expansion rapidly converges and allows calculation of combinations of wires for which specific higher order terms cancel, as we have seen earlier for the spherical harmonic case.

One useful arrangement²⁷ places four wires carrying current in the same direction symmetrically about the origin. If $\phi = 22.5^\circ$, the ‘trapezoidal’ design of Bangert and Mansfield shown in Figure 3 is obtained, when return paths are included. This design is compact, of low inductance, has low fringe fields, and offers good access. However, its efficiency is low ($2.62 \times 10^{-7}/a^2 \text{ T m}^{-1} \text{A}^{-1}$) and the volume of uniform gradient is restricted to within a sphere of radius $0.4a$.

Figure 3 ‘Trapezoidal’ transverse gradient coil

Figure 4 ‘Anderson’ longitudinal gradient coil. The z direction is taken to be the same as B_0

A further class of coils formed from straight wires was originated by Anderson.²⁸ These are suited to a transverse geometry, being mountable on the pole faces of an electromagnet in which configuration they offer excellent access. A typical example, the counterpart of the Maxwell pair, is an arrangement of four infinite wires at the corners of a square, with currents alternating in direction around the square (Figure 4). This coil, corrected up to fifth order, gives a linear G_z out to about half of the wire separation. It has an efficiency of $\eta = 10^{-7}/a^2 \text{ T m}^{-1} \text{ A}^{-1}$, noticeably poorer than that of the Maxwell pair. There are two reasons for this; firstly, the wire spacing in the z direction is somewhat greater, and secondly, the straight wire paths are generally further from the volume of interest at the origin. This instructive comparison demonstrates the importance of keeping gradient coils compact.

Anderson coils have been used extensively²⁹ where simplicity of design and construction have outweighed efficiency and risetime in importance.

6 COILS WITH DISTRIBUTED WINDINGS

As early as 1951, Garrett¹⁹ mentioned the ‘well-known precision of a cylindrical winding’ by comparison with a discrete Helmholtz pair. Coils wound to approximate a continuously varying current density on formers of simple symmetry, such as cylindrical shells or planes, generate much smaller undesired, rapidly varying, high-order fields in conjunction with the desired slowly varying terms. This means that more compact coils can be used to give gradients uniform over a given volume, so that much higher efficiency is possible. Furthermore, the inductance of such coils is in general lower, because the current density is less concentrated, and hence there is less of a field build-up in the space around the conductors.

A number of approaches to the problem of finding optimal positions for the multiple windings of such coils have been pursued. These include matrix inversion techniques, ‘stream function’ methods, and the ‘target field’ approach developed by Turner and followers. Usually such methods initially derive, by some optimization technique, a continuous current density on a coil former, such as a cylinder. A simple approximation is then used to convert this into a pattern of discrete current paths, so that a real coil may be constructed.

6.1 Matrix Inversion Methods

These methods are related to finite element methods, in that they can cope with any shape of coil former, are relatively slow in computation time, and give little physical insight regarding the dependence of field on coil configuration. Much has been written about the use of finite element methods in calculations of magnetic field distributions, and it is not appropriate to review this literature here. A few examples relevant to gradient coils will be discussed.

Hoult suggested in 1977³⁰ that a solenoid could be optimized to give a very uniform field by writing

$$B_z(z_m) = \sum_{n=1}^N A_{m,n} I_n \quad (8)$$

where

$$A_{m,n} = \frac{\mu_0 a^2}{2[(z_m - z_n)^2 + a^2]^{3/2}} \quad (9)$$

is a matrix relating the axial field $H_z(z_m)$ at a point z_m on the axis to the current I_n flowing in the n th circular loop at a position z_n of the solenoid of radius a . If N such points are chosen the matrix may be invertible, giving a set of currents at N positions which may be approximated by piling up appropriate numbers of turns at these positions. It should be noted that it is possible to specify the field in such a way that the matrix becomes singular, corresponding to an unphysical coil configuration. In practice, coils designed in this way may require large variations in current from one turn to the next, even current reversals.

At a time when the highest level of sophistication for transverse gradient coils was the use of a double saddle arrangement, Compton³¹ developed a distributed-arc coil design giving gradients departing from the desired characteristics by a predetermined error. This involved dividing the surface of a cylindrical coil former into 2048 equally sized elementary areas, and calculating the current densities which should flow in each of these areas in order to give the least-squared departure from a chosen field within a spherical volume at the center of the coil. A set of n simultaneous equations was derived, which was solved by matrix inversion or Gaussian elimination to give the surface current elements. Current paths were deduced by integrating over the elements of surface area until the current required by the coil designer to flow in a discrete wire is accumulated, at which point a conductive path is laid on the cylinder.

This approach led to high-quality transverse and longitudinal gradient coil designs,³¹ which are optimal in the sense that they give the most uniform field over the volume of interest possible for a coil of a prescribed extent (length in the case of a cylindrical coil). The computation is very slow, however, since a 2048×2048 matrix must be inverted. Furthermore, neither inductance nor power dissipation is constrained, so that optimal trade-offs cannot be explicitly obtained.

Further improvements in this approach were made by Schweikert et al.³² and Wong et al.³³ Schweikert used a Lagrange multiplier formalism to allow the field specified at N selected points in space to be used as constraints in an explicit minimization of the power dissipated by a coil (in the case

described, a solenoid). This method was used to produce an excellent low power dissipation solenoid, capable of switching 1.2 T in 400 μ s, and of high homogeneity, and can be applied to gradient coil design.

Wong et al.³³ took another approach, closely related to that of Compton. Instead of calculating optimized currents at specific surface elements, they kept the current and the number of turns fixed, while the current element *position* was allowed to vary. The error function was then minimized using the method of conjugate gradient descent, about 20–200 iterations being required. The product of the error function and the inductance could also be minimized, giving coils which are compact as well as giving gradients accurate over a large volume. For a longitudinal gradient coil, where the number of wire positions is small (10–50) the calculation takes only a few minutes on a small computer.

The chief advantage claimed for this method is that there is no stage of approximation between a calculated continuous current density and the practical realization of discrete current paths (see below). Thus the fields predicted by the calculation should be identical to those produced by the actual coil. This advantage is not significant, however, in coils with as few as 20 turns, because the field from an array of wires approximating a current sheet converges very rapidly to that of the current sheet as the number of wires increases.

For coils of very few turns to be constructed using wire rather than etched copper sheet, it is clear that the Wong technique is optimal in that it will give the best coil possible for that number of turns, and also takes a relatively short time to perform the calculation. However, computation time increases rapidly with the number of turns, unlike the continuous current density techniques to be described below which use the symmetry of the coil former radically to simplify the calculation of the fields. Furthermore, the technique does not lend itself to the design of coils consisting of copper sheet with etched or machined tracks between successive turns, which generally dissipate less power than wire coils.

6.2 Stream Function Methods

The stream function $I(z, \phi)$ on a cylinder is that function which, if differentiated with respect to z or ϕ , gives the current density in the azimuthal or axial direction, respectively. Stated otherwise, $I(z, \phi)$ is the integral of the current density. If a continuous current density distribution is to be approximated by discrete wires, the obvious place to locate them is at equally spaced contours of the stream function. Analogous definitions can be given for stream functions on surfaces of other geometries.

A number of successful distributed-arc coil designs have been obtained by considering the most simple stream functions capable of generating gradient fields of the desired symmetry. Take, for instance, the function (Figure 5)

$$I(z, \phi) = \begin{cases} \left(\frac{I_0 z}{d}\right) \cos \phi & (|z| < d) \\ \left[\frac{I_0(c-z)}{(c-d)}\right] \cos \phi & (d < |z| < c) \\ 0 & \text{elsewhere} \end{cases} \quad (10)$$

This has the correct symmetry to generate a transverse gradient and if d and c are sufficiently large the field generated is a linear G_x gradient over a large volume. This arrangement is the transverse gradient coil equivalent of a uniform solenoid, with no end corrections to compensate for its finite length.

To determine the arc positions, we have only to find the equally spaced contours of this function. For instance, for $|z| < d$, dividing the total current I_0 into N turns, the locus (z, ϕ) of the n th contour is given by

$$\left(n + \frac{1}{2}\right) \frac{I_0}{N} = \left(\frac{I_0 z}{d}\right) \cos \phi \quad (11)$$

i.e.

$$\phi = \cos^{-1} \left\{ \frac{(n + \frac{1}{2})d}{Nz} \right\} \quad (12)$$

The factor $(n + \frac{1}{2})$ is used rather than n when the coil is to be formed from wire, since this ensures that the wire is positioned at the center of the equivalent strip of current density for which it is an approximation.

Alternatively, a coil may be constructed by cutting tracks of constant width in a continuous conducting sheet, which then separates the conductor into turns of varying width. In this case the factor to be used in equation (12) is simply n . This approach has formed the basis of coil designs by Edelstein et al.³⁴ and Sutherland.³⁵ Adjustment of the parameters d and c allows some degree of optimization. The method gives rise to coils of good efficiency when sufficiently short, but the gradient homogeneity tends to be poor under these circumstances, good to 5% only within a volume of radius $0.4a$ because there is no end correction. In MRI applications the resultant image distortion is corrected in software, using a look-up table describing the known gradient field inhomogeneities, a strategy which has limitations when gradients are used for other purposes besides imaging, such as the measurement of water diffusion.¹⁰

6.3 Target Field Methods

A powerful method of designing coils, in which Ampere's law is inverted in order to calculate the currents required directly from the specification of the desired fields, has been termed the target field approach.³⁶ It relies, like the inversion of many integral equations, on the Fourier transform, and thus

Figure 5 Stream function $I(z, \phi)$, for $\phi = 0$, for Edelstein-type transverse gradient coil

can take full advantage of the speed and ease of implementation of the Cooley–Tukey finite Fourier transform (FFT) algorithm.³⁷

The starting point is to assume that the source of the magnetic field is a current density, $\mathbf{J}$, on a shell of simple geometry, such as a cylinder of circular or elliptical cross-section, a plane, or a sphere. The shell may have finite thickness, as long as the current distribution across the thickness is specifiable. The next step is to consider the Fourier transform of $\mathbf{J}$, denoted $\mathbf{j}$. For currents lying in a thin cylindrical shell, this is written

$$j_z^m(k) = \frac{1}{2\pi} \int_{-\pi}^{\pi} d\phi e^{-im\phi} \int_{-\infty}^{\infty} dk e^{-ikz} J_z(\phi, z) \quad (13)$$

$$j_\phi^m(k) = \frac{1}{2\pi} \int_{-\pi}^{\pi} d\phi e^{-im\phi} \int_{-\infty}^{\infty} dk e^{-ikz} J_\phi(\phi, z) \quad (14)$$

where J_z and J_ϕ are the orthogonal components of the current in the surface, related by the equation of continuity $\nabla \cdot \mathbf{J} = 0$. This implies that

$$j_\phi^m(k) = -\frac{ka}{m} j_z^m(k) \quad (15)$$

where a is the radius of the former. Expanding the field variation in cylindrical harmonics, the following result is obtained:^{36,38,40}

$$B_z(r, \phi, z) = -\frac{\mu_0 a}{2\pi} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dk e^{im\phi} e^{ikz} |k| j_\phi^m(k) \times K'_m(|k|a) I_m(|k|r) \quad (16)$$

where $I_m(x)$ and $K_m(x)$ are the modified Bessel functions.³⁹ These functions are easy to calculate and monotonic. Writing

$$B_z^m(r, k) = \frac{1}{2\pi} \int_{-\pi}^{\pi} d\phi e^{-im\phi} \int_{-\infty}^{\infty} dk e^{-ikz} B_z(r, \phi, z) \quad (17)$$

we can invert equation (16) for a specified $r = c$:

$$j_\phi^m(k) = -\frac{B_z^m(c, k)}{\mu_0 a |k| K'_m(|k|a) I_m(|k|c)} \quad (18)$$

Thus if the axial field B is specified everywhere on a cylinder of radius c which allows the Fourier transform $B_z^m(c, k)$ to be evaluated, the current density required to generate this field can be immediately deduced from a Fourier transformation of $j_\phi^m(k)$. Once this is calculated, the stream function can be evaluated, and the positions of wires or tracks to be removed from a continuous conducting sheet can be easily determined. This is illustrated in Figure 6, showing the integrated current density required to produce a good quality z gradient field. Many useful coil designs have been generated by these means.^{36,41}

In a similar way^{42–44} target field equations may be derived in Cartesian coordinates, relating the current densities on planes to the field produced. This results in flat transverse gradient coil designs giving more uniform gradients than those produced by simply flattening out a cylindrical coil design.⁴⁵

These equations, which may be generalized for arbitrary frequency, provide useful tools for gradient coil design. For instance, the power dissipation P in a coil consisting of a cur-

rent density flowing in a cylindrical conductor of thickness t and resistivity ρ may be written in the form

$$P = \frac{\rho a}{t} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dk |j_\phi^m(k)|^2 \left(1 + \frac{m^2}{k^2 a^2}\right) \quad (19)$$

and the energy $E = LI^2/2$ stored in the field may be written^{18,46} as

$$E = -\frac{\mu_0 a^2}{2} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dk |j_\phi^m(k)|^2 I'_m(|k|a) K'_m(|k|a) \quad (20)$$

Such quadratic expressions lend themselves to constrained minimization, similar to the approach of Schweikert mentioned earlier. Either P or E , or a suitably weighted sum of the two, can be minimized whilst the coil efficiency is held fixed at a desired selection of points in space, introduced using Lagrange multipliers. A matrix equation results, which can be solved by Gaussian elimination, matrix inversion, or singular value decomposition. The important point to note is that the matrix has dimensions $N \times N$, where N is the number of points at which the field is constrained. To obtain coils which are entirely adequate for MRI and MRS, a small number of target points is sufficient, perhaps eight. Once the Lagrange multipliers are known, the current density j can be easily derived and winding positions determined as before.

This technique, as described, places no direct restriction on the overall length of the coil, which may cause problems where space is restricted. However, a further set of Lagrange multipliers, representing length constraints, may easily be added.⁴⁸ This allows straightforward truncation of coils, still with the guarantee of minimum inductance or power consistent with the constraints applied.

Similar expressions may be derived for currents flowing on planes. Minimum inductance planar designs have been developed by Martens et al.⁴⁴ and minimum power designs by Bowtell and Mansfield.⁴²

Figure 6 Integrated current density on the surface of a cylinder radius a required to produce a uniform longitudinal gradient over a volume of interest radius $0.7a$, length $1.0a$. Arrows indicate positions, at equal increments of integrated current, where wires would be placed to approximate this current density in a practical implementation. Note single reverse turn (–) (Reproduced by permission of *Magnetic Resonance Imaging*)

These methods of coil design can be implemented on a relatively small computer, and if the fast Fourier transform is used to calculate the matrix elements, as well as to evaluate the current densities, a computation time of a few minutes is all that is needed, even if a large array of points (say 2048) is used. The winding pattern and the field distribution can be computed at thousands of points in space in a few seconds, using equations (17) and (18). It is recommended to use extended precision to ensure stable results.

A similar approach using spherical harmonics has recently been devised.⁴⁷

6.4 Apodization

With minimum inductance and power dissipation designs, it is often desirable¹⁸ to remove the most rapidly varying current components by 'apodization'. This involves multiplication of the calculated $j(k)$ by a Gaussian function before it is Fourier-transformed back into real space to give the current distribution. The effect, for apodization lengths of about one-tenth of the coil radius, is to smooth out the field variation at a negligible cost in conformity to specifications while reducing the inductance slightly, and removing the undesirable current density oscillations.

6.5 Comparison of Minimum Inductance and Minimum Power Designs

Minimum power designs are less compact than minimum inductance coils and their inductance is about 10% higher, but they have a smoother variation of current density and a lower power dissipation⁴⁸ (Figure 7). If minimizing coil risetime is the primary objective the minimum inductance approach is best, but if the space available for coil windings is limited radially the minimum power approach is preferable.

7 PASSIVE AND ACTIVE SHIELDING

One of the major problems in the use of switched magnetic field gradients in MRI and MRS has been the interaction of the rapidly switched fields with other conducting structures in the magnet assembly. Such structures may include heat shields in the Dewar holding the superconducting magnet, supports for these heat shields, and also radiofrequency coils and local rf shielding. Eddy currents are induced in these structures, which produce fields opposing that of the switched gradient. The behavior of the gradient fields at the center of the magnet is degraded, both temporally and spatially. The rise time of a switched gradient is increased and transient currents which are slow to decay may cause a long settling time.

A somewhat crude solution to this problem is to adjust the gradient waveform which is fed to the gradient amplifiers so as to compensate for the effect of induced eddy currents.^{49,50} This is often performed by adding a feedback circuit to each gradient amplifier, containing a set of appropriate resistance and capacitance values to provide up to four time constants which can be separately adjusted. Apparently clean and fast switching may thus be obtained for the gradient current. This implies increasing the voltage available for current switching and thus

Figure 7 Primary coil turn layouts for (a) minimum inductance transverse gradient coil (inductance $61 \mu\text{H}$, power dissipation 23 mW A^{-2}) and (b) minimum power dissipation transverse gradient coil (inductance $73 \mu\text{H}$, power dissipation 15 mW A^{-2}). For both designs: primary coil radius, 0.1 m ; shield radius, 0.5 m ; coil efficiency, $0.5 \text{ mT m}^{-1} \text{ A}^{-1}$; target cylinder radii, 0.01 m , 0.06 m ; axial spacing of target points, 2.5 mm ; number of target points per cylinder, 5 ; copper thickness, 1 mm

adding to the cost of the gradient drivers. But a more serious problem remains. The eddy currents induced by switching do not disappear simply because compensation has been applied. They may persist for many milliseconds after the gradient current has stabilized at a new level, producing time-varying distortions in the gradients experienced at the sample as we have mentioned. These fields can produce major distortions in NMR spectra, prevent the use of short echo times in fast imaging, and render diffusion imaging, which uses large precisely-matched gradient pulses, completely impossible.

The best way to solve this problem, as pointed out by Chapman and Mansfield^{51,52} and Roemer and Hickey,⁵³ is to avoid the occurrence of eddy currents altogether, by using gradient coils which do not have fringe fields and rf coils which

will not support persistent eddy currents. Such gradient coils consist of an inner ‘primary’ coil, which supplies most of the gradient, surrounded by a ‘screen’ or ‘shield’ coil, which is designed to cancel exactly any field from the primary coil outside the screen.

The mathematics for the calculation of screen coils in a cylindrical geometry^{38,51} relies on the expansion of the magnetic field in cylindrical harmonics [equation (16)]. If a second coil of radius b is added, the total field outside the coil becomes:

$$B_z(r, \phi, z) = -\frac{\mu_0 a}{2\pi} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dk e^{im\phi} e^{ikz} |k| j_\phi^m(k) I'_m(|k|a) K_m(|k|r) \\ + \frac{\mu_0 b}{2\pi} \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} dk e^{im\phi} e^{ikz} |k| J_\phi^m(k) I'_m(|k|b) K_m(|k|r) \quad (21)$$

where $J_\phi^m(k)$ is the Fourier transform of the current in the screen $J(\phi, z)$. For the field outside the screen to be zero, a necessary and sufficient condition is that

$$J_\phi^m(k) = -\frac{a I'_m(|k|a)}{b I'_m(|k|b)} j_\phi^m(k) \quad (22)$$

Thus, given a particular primary coil current, the continuous current needed for screening may easily be calculated using two Fourier transforms. Finite element calculations⁵⁴ give substantially the same results as expected, but with much longer computation times.

Generally speaking, the field produced by the screen coil perturbs that of the primary, so that the net field diverges from what is desired. The primary coil may either be redesigned in a somewhat ad hoc way,³⁸ or another approach, the ‘integrated design’, may be adopted.

This method is an extension of the target field method. The field is now specified on two target surfaces and the current densities $J(\phi, z)$ and $j(\phi, z)$ on two coil formers are taken as unknowns. As an illustration, consider a primary cylindrical coil of radius a and a screen coil of radius b . Taking the first target surface as an inner cylinder of radius c at which the desired gradient is specified, and the second target surface at the radius of the screen where the field is set to be zero everywhere, we obtain two simultaneous equations for the Fourier transforms of the current densities which are easily solved, giving^{55–57}

$$j_\phi^m(k) = \frac{-B_z^m(kc)}{\mu_0 b k I_m(|k|c) [K'_m(kb) - \{I'_m(|k|b)/I'_m(|k|a)\} K'_m(ka)]} \quad (23)$$

$$J_\phi^m(k) = -\frac{a I'_m(|k|a)}{b I'_m(|k|b)} j_\phi^m(k) \quad (24)$$

Here $B_z^m(kc)$ is the Fourier transform of the desired target field at the radius c of the target cylinder.

These results provide complete specifications for a coil with prescribed field variation in a defined region within the primary coil, and zero fringe field outside the screen. The mathematical formalism will of course support many other configurations, for instance a prescribed field outside the screen and zero field inside the primary. Furthermore, the operation can be carried

out for other coil geometries, such as coils formed on parallel planes⁵⁷ or cylinders of elliptical cross section.⁵⁸

Preferably, the active gradient shield should be made from a continuous conducting sheet, with a narrow slot formed in it constraining the current to follow the appropriate path. In this way a closer approximation to the continuous current density really required can be obtained than by using discrete wire. However, such a configuration gives a degree of shielding which varies with frequency, owing to changes of the current distribution within the width of the conducting paths. Even at the highest frequencies, when this problem is most severe, the shielding from a slotted continuous shield is better than with discrete wires. A further recommendation is to arrange the wiring of the shield in series with the primary coil, to ensure that the current changes in each are in phase. There are further engineering details outside the scope of this article. It has generally been found that active shields are not 100% effective in practice, reducing the fringe fields to at best 1% of the unshielded values. Eddy current compensation circuits continue to be advisable, although the current and voltage requirements of these devices are drastically reduced. Using a combination of active shielding and eddy current compensation, gradient settling times can be reduced to a few hundred microseconds.

8 COIL PERFORMANCE

Using the minimum inductance algorithm, it is possible to create plots defining optimal gradient performance as a function of primary and active shield coil radius, and coil length.

Figure 8 shows the dependence of inductance on primary coil radius for fixed coil efficiency at target points, spaced proportionately to the primary coil radius, and fixed shield radius,

Figure 8 Calculated effect of increasing primary coil radius on the inductance of a transverse gradient coil while keeping shield coil radius and coil efficiency fixed. The spacing of the target points chosen was kept proportional to the primary coil radius. Without shielding this would give geometrically similar designs with inductance proportional to the fifth power of the radius, shown by the asymptotic straight line fit on this log–log plot

Figure 9 Calculated effect of coil length on inductance for a truncated minimum inductance transverse gradient coil. The target points, efficiency, primary coil radius, and shield radius are all kept fixed

for a minimum inductance transverse gradient coil. The straight line represents the fifth power dependence expected without shielding. The divergence of the inductance as the primary radius approaches that of the shield is evident, and represents a serious limitation inherent in active shielding. More and more magnetic energy comes to be stored between the primary and shield radii as they approach each other, and the number of turns of conductor on each also diverges causing major problems in fitting conductors of adequate cross-section into the available space.

Figure 9 shows the effect of coil length on inductance in a truncated minimum inductance transverse gradient coil design, in which the length of the coil is used as a further constraint in the constrained inductance minimization algorithm. Here the efficiency is kept fixed and fixed target points are used. As the coil is shortened the inductance diverges, corresponding to the increasing proximity of the windings generating the desired gradient and the return paths, which tend to cancel this gradient. For fixed efficiency, the total number of turns needed thus increases rapidly as the coil is shortened, thereby increasing the inductance. If very short transverse gradient coils are required, the only practical recourse is to put the return paths at an increased radius, as described in the next section.

Finally, Figure 10 shows the effect on the coil inductance of changing the shield radius keeping the primary coil radius, the target points, and the efficiency fixed. The divergence of the inductance as the shield approaches the primary is clearly seen. It is interesting to note, nevertheless, that the effect of the shield is actually to reduce the inductance of the coil about which it is placed.

9 UNORTHODOX DESIGNS

Having outlined the various mathematical techniques which have been used to design good gradient coils, we will now consider the constraints of patient access and mechanical de-

Figure 10 Calculated effect of change of shield radius for a minimum inductance transverse gradient coil for fixed primary coil radius, target points, and efficiency

sign. Patient access is an issue because of the a^5 power law problem; it pays to make coils as small as possible. Hence special coils fitting snugly round the head have been developed.⁵⁹ These allow echo planar imaging (EPI), and also enable ultrathin slices and short echo times to be achieved.

The longitudinal gradient is easy; a Maxwell pair (see above) or a modification^{59,60} with better linearity is short enough to provide good gradient fields in the brain and brain stem while resting on the shoulders. However, transverse gradient coils of conventional design cause serious access problems. Several solutions have been proposed. The first is to use a target field design, truncated as far as possible without decreasing the efficiency intolerably, and then to distort the current return paths to provide shoulder slots. Another, more radical approach, was proposed by Turner and implemented by Myers and Roemer⁶¹ and others. This consists of taking only one-half of a conventional transverse gradient coil design, the positive z -axis section say, to give an asymmetric coil with a region of interest with approximately linear gradient close to one end.⁶² The unbalanced torques in such an arrangement, which may cause serious mechanical stability problems, can be avoided by providing additional counterbalancing current paths at the expense of increased coil inductance.⁶³ A related effective stratagem is to design a symmetrical coil, using the target field method which provides uniform gradients at both ends, only one of which is used for imaging. Again, this gives a higher inductance.

Yet another solution is provided by designing a very short, heavily truncated, conventional double saddle 'fingerprint' transverse gradient coil.⁶⁴ The difficulty with this approach is that the gradient uniformity is inevitably rather poor in the axial direction, and the coil efficiency is also low because the current return paths are close to the active sections. The best solution is to arrange the return paths on a former of larger radius, so that they partially screen the active turns. A first step in this direction has already been made, by Bangert and Mansfield, as described earlier,²⁷ though the volume of uniform gradient in this coil is rather small and its efficiency is low. Very recently Wong and Hyde⁶⁵ have used the conjugate gra-

dient descent method to develop such a design on a pair of concentric cylinders, and Brey et al.⁶⁶ have developed an elegant coaxial design made from identical modular elements.

If easy access to the interior of the gradient coils is not required, the approach of Lowe⁶⁷ has some merit. Here the idea is to approximate by wires the continuous current density on the surface of a sphere required to generate the single spherical harmonic terms which represent each of the three orthogonal linear gradients needed. Such coils give excellent gradient fields everywhere inside the spherical former and are also maximally efficient.

For body imaging, flat gradient coils, either alone⁴⁵ or paired,⁴²⁻⁴⁴ offer better access and efficiency than cylindrical coils of circular section, because they can be placed closer to the body. The ideal configuration is probably coils wound on a cylindrical former of elliptical cross-section.⁵⁸

10 COIL FABRICATION METHODS

Several methods have been used to translate curvilinear coil designs which are sometimes quite complicated into practical pieces of equipment. Coils built from discrete wire often utilize a guide slot machined into a nonconductive (e.g. glass-reinforced plastic) cylindrical former. The complex curve is generated using a computer-driven lathe or milling machine. The wire is then laid in this slot and bound in place with a further layer of resin-soaked glass fiber. Sometimes very heavy gauge rectangular-section copper wire is used, typically for 'Golay' type double-saddle coil arrangements in which the coil is almost self-supporting. For coils formed from slotted continuous copper sheet, various methods are used for forming the slot. The simplest is to use a machine fretsaw, although this carries the risk of coil distortion as the sheet of copper becomes progressively more delicate. A computer-driven milling machine or high-speed punching machine can also be employed, allowing thicknesses of copper of more than 1 mm to be utilized. The quickest method is undoubtedly to use a printed-circuit board technique,³⁴ in which a layer of photoresist is deposited on the copper sheet and the slot is formed by etching out the track photographically marked in the photoresist. This method is feasible only for a limited thickness of copper.

A full discussion of manufacturing tolerances is out of place in this review which focuses primarily on mathematical methods. However, it needs to be stated that for distributed winding designs, random positional errors of 0.5% of the former radius cause no significant errors in the gradient homogeneity obtained.

11 SUMMARY AND CONCLUSIONS

Gradient coil design has reached a level of some maturity. The limitations imposed by the Laplace equation and material parameters such as conductor resistivity have become clearly definable. Coil design algorithms have been implemented which optimize a variety of coil features, such as stored energy, dissipated power, and combinations of the two. Coils may be constrained to produce fields precisely specified at

points, on surfaces, and within volumes as the integrated least-square departure from a desired configuration. Coil formers may be flat, cylindrical, ellipsoidal, or even more irregular, though for most rapid computation and evaluation Cartesian or cylindrical geometries are preferred, enabling the power and speed of the fast Fourier transform to be utilized. The new generation of gradient coil designs has opened the way to new and powerful magnetic resonance techniques, such as echo planar imaging (EPI, q.v.), diffusion imaging, and gradient editing of multinuclear spectra.

Multifrequency Coils for Whole Body Studies

Joseph Murphy-Boesch

USA Instruments Inc., Aurora, OH, USA

1 INTRODUCTION

In whole body MRI, the dominant hydrogen resonances of water and fat provide a wealth of information which may be used to diagnose conditions associated with bone and soft tissues. Important biochemical and physiological information, however, may be derived from the resonances of other naturally occurring nuclei, such as phosphorus (^{31}P), carbon (^{13}C), sodium (^{23}Na), and deuterium (^2H), exogenous nuclei, such as fluorine (^{19}F), and the weaker resonances of hydrogen (^1H) or protons. These resonances can be used to identify important metabolites, measure metabolite concentrations, tissue pH, and metabolite rate constants, and provide information on molecular structure and binding. Because the sensitivity of these low- γ -emitting nuclei is low (with the exception of fluorine), coils must be positioned and tuned close to the tissue being observed. Because human spectroscopic data are generally acquired in the context of an integrated imaging/spectroscopy examination, multifrequency coils offer distinct advantages over single-frequency coils. For example, MR images are used early in the examination to identify a tissue region for localization and later during processing for registration of spectroscopic data with anatomy. Localization techniques are employed to enhance signals from a specific region of tissue and attenuate signals from outside (see *Spatial Localization Techniques for Human MRS*).

Before acquiring spectra from phosphorus and other 'low- γ ' nuclei, it is generally necessary to adjust static magnetic field homogeneity on a strong and pervasive resonance such as that of water. For simple protocols involving more than one nucleus, it may be sufficient to switch coils or retune the coil during the examination. This, however, usually involves movement and repositioning of the subject, and to expedite the examination, it is generally preferable to position the subject and tune the NMR probe once at the beginning. When acquiring ^{31}P or other nuclei that are coupled to protons, it may be desirable to transmit at the proton frequency simultaneous with acquisition of the ^{31}P signal to decouple the proton resonance. To implement this double resonance sequence requires a dual-frequency coil that conforms to anatomy together with filtering and other specialized receiver circuitry to remove interactions between the two active radiofrequency (rf) channels.

2 GENERAL DESIGN CONSIDERATIONS

According to Hoult and Richards, who first recognized the principle of reciprocity for NMR, the sensitivity of a coil at a selected location can be gauged by the strength of the B_1 field

produced by a unit of current I in the coil.¹ Thus, the signal induced in a coil by a small volume of sample is proportional to the product of the volume and the normalized field, $b_1=B_1/I$. To carry this one step further, coil sensitivity is reflected in the rate, $\omega_1=\gamma B_1$, by which nuclei are nutated about the B_1 field in the rotating frame, i.e. the efficiency of the transmitter in producing a 90° pulse. They further showed that sensitivity could be related to the ratio $B_1/\sqrt{R}$, where R is a series resistance which incorporates all coil and sample related losses. Coil sensitivity can thus be 'mapped', either theoretically with a computed B_1 profile, or empirically with measurement of 90° pulses at each location. Much analysis of sensitivity and transmitter efficiency for single and multiply tuned high-resolution and solid state probes has been published¹⁻⁵ (see *Sensitivity of the NMR Experiment*). This analysis is relevant for the large volume coils of high-field, whole body instruments, and has been extended to include the strong conductive and dielectric loading associated with tissue.⁶ While conductive losses from eddy currents induced in tissue are unavoidable, losses associated with electric field couplings may be reduced by careful attention to coil geometry and circuit design⁷ and use of distributed capacitance.⁸ A review of basic principles of probe design, circuit techniques and performance measurement can be found in the monograph by Chen and Hoult⁹ (see *Sensitivity of Whole Body MRI Experiments*).

Another design consideration has to do with the physics of nuclear induction. Nuclei nutate, or 'flip', their orientations with respect to the static field as a result of a *circularly polarized* component of the B_1 field. In the rotating frame this is a field of slowly changing amplitude which rotates with the same sense as the precessing nuclei. A single, 'linearly polarized' coil can be used to excite and detect nuclei, because it produces both left and right circularly polarized fields simultaneously, one component of which has the correct sense of rotation. In a frame with a z oriented static, or B_0 , field, two or more such 'linear mode' coils can be oriented to produce linearly polarized fields which are transverse to one another, as indicated in Figure 1(a,b). Sample geometry often makes it possible to construct such 'crossed-coil' arrangements, in which two coils have little magnetic coupling, providing electrical isolation of their tuned circuits. These circuits may be tuned either to different frequencies, permitting excitation and detection of different nuclei, or to the same frequency, to provide quadrature excitation and reception. Upon transmission in quadrature phase, the latter will produce minimally an elliptically polarized field and, ideally, a circularly polarized B_1 field in the tissue region of interest.

In another configuration, two coils can be aligned with one another as they are for the concentric coils shown in Figure 1(c). These coils have strong inductive coupling and, by Faraday induction, the smaller, inner coil will oppose the field of the larger coil and shield its interior. This shielding may be eliminated by passive or active circuits which increase the impedance of the smaller coil. For coils tuned to widely separated frequencies, B_1 flux from the outer coil can circumvent the inner coil and excite the region below it. For loops tuned to approximately the same frequency, strong coupling or 'over-coupling' of the two resonant loops will produce new resonant modes. Alternatively, these modes may be exploited to produce a multiresonant rf coil, as discussed below.

Figure 1 (a) A volume crossed coil with coil pairs A-A' and B-B' oriented to produce transverse linearly polarized B_1 fields at two frequencies, (b) a planar crossed-coil configuration to produce transverse fields below the coil, and (c) two concentric coils which produce colinear fields along the central axis

Many design possibilities exist for multiply tuned probes. They can employ a single sample coil which is part of multiply resonant circuit or multiple resonant coils, each of which produces B_1 flux in the sample. Connection to the coil can be made in the form of single or multiple ports and coupling to the resonant modes can be either inductive or capacitive. The operational modes of individual coils within a probe can be transmit only, receive only, or both. Finally, while a single coil provides only a linearly polarized field, the availability of additional coils or modes within a complex resonator can provide quadrature or circularly polarized operation. With sensitivity being a primary design consideration, the constraints which limit design possibilities will often be the shape of the body and the limited space within the magnet. There is also an interplay between the particular sequence of rf pulses, gradients, and acquisition intervals and the design of the probe. For

example, the limited B_1 profile of a surface coil can provide a measure of localization in two dimensions, with localization in the third dimension provided by slice selection which uses the B_1 gradient of the coil (see *Rotating Frame Methods for Spectroscopic Localization*).

3 MULTIPLE TUNING TECHNIQUES

3.1 Multiple Tuning Using a Single Sample Coil

An economical way of performing multiple frequency NMR is simply to switch or retune the elements of a single sample coil. There are various ways of accomplishing this. With the coil mounted at the end of a flexible, low-loss transmission line, tuning elements can be placed well away from the subject.¹⁰ The coil is then easily positioned on the subject, and tuning may be switched remotely, although some loss in sensitivity can be expected from cable resistance. Alternatively, a box containing tuning and matching circuitry can be inserted at the end of a length of cable connected to a probe pretuned for a single frequency,¹¹ although this generally results in loss of sensitivity for the second nucleus. All these methods, of course, permit only sequential use of the probe for each nucleus and may require movement and repositioning of the subject, lengthening examination time.

More commonly, a single sample coil provides an adequate field-of-view and adequate sensitivity for the detection of two or more nuclei and may be multiply tuned to observe them. Methods for multiple tuning high-resolution and solid-state probes using resonant sections of transmission lines¹² and parallel and series resonant L-C 'trap' circuits^{4,13} are well developed. These are multiple port designs which use one port for each nucleus, and are readily adapted for use with a surface coil. With the motivation of reducing the number of reactive components in a multiple tuned probe, Schnall et al.¹⁴ proposed using simpler, impedance modifying networks which substitute for the capacitor of a simple resonant L-C circuit, as indicated in Figure 2(a). The composite element shown in Figure 2(a) presents a negative (capacitive) impedance to the sample inductor at two frequencies resulting in two resonances. Circuits of this type have been recognized as 'Foster networks', after R. M. Foster¹⁵ who demonstrated that any purely reactive network must necessarily have a driving point impedance which alternates between zero and infinity. Multiple tuning of a sample coil for $N+1$ frequencies can be achieved using a composite circuit of N traps, as indicated in Figure 2(b). The sensitivity of this circuit is reduced by resistive losses of the additional trap circuits. Since these losses tend to be concentrated in the series resistances of the trap inductors and since the majority of current for the low-frequency mode flows through these inductors, the low-frequency mode tends to suffer the greatest loss in sensitivity compared with the single resonant circuit. In general, there are many more configurations for multiple tuning a sample coil than indicated in Figure 2(b), and the possibilities grow rapidly with the number of NMR frequencies resonances to be observed (see also Schnall et al.,¹⁴ Figures 7 and 8, and Foster,¹⁵ Figures 1 and 2). Methods for multifrequency coupling to these probes are not well described. It is apparent, however, that a single matching capacitor can be replaced with the composite network shown

Figure 2 (a) Double tuning of a simple resonant circuit by replacement of the tuning capacitor with a composite circuit element. Capacitors C_{lf} and C_{hf} are used to tune the low frequency and high frequency, respectively. (b) Use of a Foster network to multiple tune a single coil for $N + 1$ frequencies

in Figure 2(a) for single port matching at two frequencies: a more complex composite network would be used for three or more frequencies. This type of matching is efficient, since any losses in coupling in the coupling network are typically in series with a $50\ \Omega$ source impedance of the rf system.

If an additional ‘odd’ impedance element is added to the four circuit elements in Figure 2(a), one obtains a circuit of different characteristics. For example, the odd element can be the coupling element between two resonant L–C or ‘tank’ circuits of approximately the same frequency, as indicated in Figure 3. This coupling can be capacitive or inductive or take the form of the mutual inductance between the resonant inductors. If the coupling is strong, the modes of the two resonant circuits tuned to the same frequency will split into two new distinct modes. This effect is referred to as overcoupling, and Schnell et al. have shown that overcoupled tank circuits can be applied to the acquisition of two and even three nuclei.¹⁶ The motivation for using the overcoupled circuit was to tune resonant modes for nuclei with closely spaced frequencies, such as ^1H and ^{19}F or low- γ nuclei such as ^{13}C and ^{31}P . Another characteristic of an overcoupled circuit using inductive coupling is that little current tends to flow through the coupling inductor in the low-frequency mode. Thus, the situation with regard to sensitivity is reversed compared with the double tuned circuit shown in Figure 2(a), with the lower frequency mode suffering less of a loss in sensitivity compared with the higher frequency mode. Grist et al.¹⁷ have reported an over-

coupled resonator assembled with two identical resonant loops coupled primarily by their mutual inductance. The modes of the coil can be resolved into corotating and counterrotating modes, according to the sense of circulation of the currents, and these modes can be tuned separately for the ^{31}P and ^1H frequencies, respectively (see *Surface and Other Local Coils for In Vivo Studies*). The lower loop residing close to the tissue surface produces most of the B_1 flux within the tissue. Because of its greater distance from the tissue, the upper loop has less of an effect upon the B_1 field of the coil, providing a small positive contribution at the ^{31}P frequency and a small negative contribution at the ^1H frequency. With the greater tissue loading encountered at the ^1H frequency, little loss in sensitivity is generally experienced at either frequency compared with single resonant coils of the same size.

3.2 Multiple Tuning using Multiple Sample Coils

A straightforward method of implementing multiple frequency spectroscopy on a clinical instrument is to use the body coil for ^1H imaging and a surface coil for spectroscopy at a second frequency. If the body coil operates in linear mode, the surface coil can be oriented transverse to it in crossed-coil configuration. When the body coil is circularly polarized, coupling between the coils is strong, and other measures must be used to decouple them. With a surface coil tuned to a much lower frequency, it is possible to image through it if the distortion to the B_1 field is acceptable. Another coil configuration which provides good image quality is one in which the body coil is used for uniform transmission and a surface coil is tuned for ^1H reception. Care must be exercised, however, to avoid excess power deposition from power absorbed by the surface coil and transmitted to the tissue.¹⁸ To prevent this, passive diode or active PIN junction diode switching must be used to detune the coil, or otherwise render it high impedance. Another method to prevent coupling to the body coil is to use the symmetric mode of a ‘counterrotating’ coil for imaging,¹⁹ since the antisymmetric mode of the coil does not couple with a uniform external field.

Multiple sample coils are often employed in whole body spectroscopy because they offer distinct advantages over single coils for integrated imaging/spectroscopy examinations. The requirements of imaging, shimming, and proton-decoupling

Figure 3 An overcoupled ‘tank’ circuit illustrating three types of electrical coupling: capacitive via C_c , inductive via L_c , and mutual inductive via M

generally dictate using a larger field-of-view for the ^1H coil. Multiple coils can be crossed-coil designs such as surface coil 'butterfly' coil combinations^{20,21} or concentric coils that use a larger coil for ^1H imaging.²² Single or multiple ports can be used to connect to multiple coils. Two-port coils take advantage of the natural isolation of crossed-coils to maintain isolation between frequencies. Single-port coils require more complicated filtering and crossover networks for double resonance experiments, since transmission at one frequency must be simultaneous with transmission and/or reception at the second frequency. Recent progress has been made in the use of multiple receiver coils, or 'phased arrays',²³ which improve sensitivity at intermediate tissue depths (see *Whole Body Machines: NMR Phased Array Coil Systems*). Application of coil arrays for spectroscopy has so far been implemented in 'receive only' mode, with larger coils being used for homogeneous excitation.²⁴

4 VOLUME AND QUADRATURE COILS

Volume coils are distinguished from surface coils by the way in which they surround the sample. Accordingly, they are used for the head, extremities, or the entire body. They offer more possibilities for quadrature operation because the coil has more ability to produce two transverse B_1 fields in the sample. While methods of multiple tuning volume coils bear similarities with methods of tuning high-resolution probes, it is difficult simply to scale upwards the dimensions of a small high-resolution coil, since the inductances become too large to resonate efficiently at fields of 1.5–3.0 T. It has generally been necessary to use wide conductors with low inductance and add distributed capacitance, such as for the Alderman–Grant coil,²⁵ to achieve coil dimensions suitable for studies of the head.²⁶ A dual frequency probe for 1.9 T has been reported which uses two linear mode, Alderman–Grant coils in the crossed-coil configuration.²⁷

An alternative to the saddle, solenoid or other high-resolution coil geometries is the birdcage resonator,²⁸ which is cylindrically symmetric and exhibits two isolated linear modes (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*). These modes are ordinarily tuned for quadrature operation at a single frequency. Joseph and Lu²⁹ have demonstrated that these modes can be tuned independently to the ^1H and ^{19}F resonances without significant loss in B_1 homogeneity by using differential capacitive loading. Since this method uses the birdcage in linear mode at each frequency, it cannot provide the efficiencies of quadrature operation. To obtain quadrature operation at the phosphorus frequency, Bottomley et al.³⁰ used a phosphorus birdcage for the head and a body coil for imaging through the phosphorus coil, thereby accepting a nominal loss in the signal-to-noise ratio at the ^1H frequency from shielding by the phosphorus bird cage. This method must be implemented with great care, since it is possible to couple considerable power from the body coil to a higher order mode of the birdcage. This caveat applies, of course, to any multimodal coil contained within the body coil. More recently, Dürr and Rauch³¹ have reported a dual tuned body coil for 4 T. The primary purpose of the phosphorus mode is to obtain homogeneous rf transmission, permitting reception by a more sensitive surface coil or phased array.

In early reports of quadrature, dual tuned volume coils, composite double-tuning elements were inserted into the legs or end rings of a standard birdcage.³² In another approach, the repeating elements of the birdcage were viewed as analogs of the repeating elements of a rf filter,³³ and these were used by Rath³⁴ to produce bandpass and bandstop configurations which could be dual tuned. These designs have not yet found routine use in clinical spectroscopy, possibly because of difficulties in tuning and mode alignment.

More recently, a four-ring birdcage design has been reported that produces homogeneous quadrature modes at two frequencies.³⁵ As shown in Figure 4, the coil contains an inner birdcage structure which shares inner rings with two outer structures of identical design. The outer structures can assume either a low-pass configuration with capacitors in the outer legs, as indicated in the figure, or a single-sided, high-pass configuration with capacitors placed only in the outer rings. The inner birdcage structure operates substantially independently of the two outer structures to produce quadrature modes for a low-frequency nucleus, such as phosphorus. The two outer structures couple strongly through the inner legs of the coil, producing corotating and counter-rotating mode pairs in the manner of overcoupled resonators. Of these mode pairs, the corotating fundamental mode produces a highly homogeneous B_1 field in the coil and can be used to obtain high-quality MR images. Sensitivity comparisons at 1.5 T with standard birdcage coils show no loss of sensitivity at the phosphorus frequency and 85–90% sensitivity at the ^1H frequency. Finally, four-ring birdcage coils tuned for ^1H and ^{31}P have been used routinely to obtain high-quality proton-decoupled phosphorus spectra from the head and leg, demonstrating that the coil can be operated simultaneously in transmit and receive modes at two frequencies.

Implementation of volume coils for very high magnetic fields (3.0–8.0 T) require new schemes. Even with distributed capacitance, coil dimensions at these field strengths become comparable to the wavelength of propagation and the coils become efficient radiating antennae. Coupling to the inner bore of the magnet and connecting cables becomes strong, and it is

Figure 4 The low-pass, low-pass configuration of the four-ring birdcage

necessary to confine the electric and magnetic fields of the coil inside a conductive shield. While shielded birdcage designs have been found to work well at up to 3.0 T, higher frequency operation requires the use of the shield as an element of a cavity resonator. A coil that performs well in this capacity is the TEM resonator reported by Vaughan and co-workers.³⁶ This coil is a 're-entrant' configuration, with transmission line elements that connect directly to the shield. It takes advantage of the natural modes of a cylindrical cavity resonator to produce a homogeneous B_1 field over the head. This configuration can be dual tuned by alternating the tuning of the transmission line elements, and both head and body coil configurations of the coil have been implemented above 4.0 T.

5 APPLICATIONS

An early motivation for using dual and triple tuned coils was simply to acquire spectra sequentially from more than one nucleus at a time. Surface coils provided a degree of spatial localization, but this localization was found to be inadequate for proper interpretation of spectra. As newer and more precise methods of localization were developed, spectroscopy was integrated with imaging examinations, so that spectroscopic data could be registered and correlated with anatomy (see *Whole Body Studies: Impact of MRS*). For this application, the spectroscopy coil required good sensitivity, and the ^1H imaging coil required both good sensitivity and a somewhat larger volume of excitation. For ^{31}P and ^{13}C human studies, improved spectral quality could be obtained with proton decoupling,^{20,21} and improved sensitivity could be obtained from NOE enhancement.^{21,37} To implement proton decoupling, greater isolation is required between the proton decoupling transmitter and the phosphorus preamplifier, either via the probe or through the use of additional filtering, to prevent noise at the phosphorus frequency from being injected into the preamplifier. This isolation is also required to prevent the preamplifier from being saturated by the ^1H signal. Transmission at the ^1H frequency can then be simultaneous with acquisition of the phosphorus signal. The reverse of these requirements would, of course, apply for the inverse experiment, that is, excitation at the low frequency and detection at the ^1H frequency. In clinical studies, especially for those which monitor treatment, it is often important to quantify metabolites in a localized volume. Tissue concentrations are usually determined by calibrating the instrument with a known standard, which is generally one of two types: an external standard or an internal standard, with water in tissue being a convenient choice for the latter.³⁸ To use water as a standard, a single, double-tuned sample coil is generally employed to eliminate the need for complicated field corrections at two frequencies.

In summary, a great many multifrequency coil designs are available for providing multinuclear capability with optimum coil efficiency at each frequency. Unlike single tuned designs, there are few generic designs which can fulfill the many requirements of spectroscopy studies. Except perhaps for the head coil and the basic crossed-coil, dual-frequency surface coil, sensitivity and the demands of integrated spectroscopy/imaging examinations often require coils that are specialized for each application.

Radiofrequency Systems and Coils for MRI and MRS

William A. Edelstein

General Electric Corporate Research and Development, Schenectady, NY, USA

1 INTRODUCTION

The MR rf (radiofrequency) system includes a waveforming and transmitting portion that applies rf magnetic field pulses to targeted nuclear spins via an rf coil. The applied field, B_1 , causes the spins to nutate (or tip) relative to the direction of the static magnetic field, B_0 . The nutated spins collectively form a transverse precessing magnetization which is picked up by the transmitting rf coil or a separate rf receiving coil. The resulting signal is amplified, mixed down to an audiofrequency, digitized, and processed by a computer which turns the signal into an image or spectrum.

Rf coils come in many shapes and sizes but can be generally characterized as *volume coils* or *surface coils*. Volume coils (e.g. a solenoidal winding) contain the sample of interest; surface coils (e.g. a simple loop) are placed on the surface of the sample. Volume coils usually produce a homogeneous rf magnetic field and have a large FOV (field-of-view), a fairly uniform sensitivity, and a moderate S/N (signal-to-noise ratio). Surface coils produce a rapidly varying rf magnetic field (strongest in their vicinity), and consequently a high S/N for a small volume of the sample near their location, and thus, effectively, a small FOV.

The NMR *phased array* is an assembly of overlapping surface coils which cover a large surface area and can have the sensitivity and S/N of a surface coil combined with the FOV

of a volume coil. They require, however, considerable complexity in the rf receiving system and system image processing capabilities.

The MR requirements for large rf coils, which operate efficiently at high frequencies, have produced a number of interesting technical advances such as the use of distributed capacitances, the *birdcage* rf coil (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*) and the NMR phased array (see *Whole Body Machines: NMR Phased Array Coil Systems*).

2 RF SYSTEM

Shown in Figure 1 are block diagrams of two typical rf systems. In general, the rf system can be divided into two parts: transmit and receive. The transmit portion sends out high-power rf pulses (milliwatts to kilowatts) which are applied to the spin system through the transmit rf coil. The NMR signal is then picked up by the transmit rf coil or by a separate receive rf coil. Figure 1(a) uses a single rf coil which both transmits (applies the rf excitation pulse) and receives (the NMR signal). Figure 1(b) uses separate transmit and receive coils.

The system computer (or a pulse programmer, which is an attached microprocessor) generates pulse waveforms which are used to modulate an rf carrier (an rf signal at constant phase and amplitude). The resulting waveform contains a high-frequency signal at the NMR frequency (typically tens of MHz) whose amplitude and phase are varied by the modulation.

Following the pulse programmer is a low-level rf transmitter (capable of power output up to tens of watts) followed by an rf power amplifier, which produces watts to kilowatts. The high-level rf signal proceeds through the T/R (transmit/receive) switch^{1,2} to the rf coil. The T/R switch is designed to let the high-level rf through during transmit but close off the rf transmit channel during receive. This is because the rf transmit channel may have appreciable noise.

The rf signal then produces currents in the rf coil and a consequent rf magnetic field, generally called B_1 (in contrast to the

Figure 1 Rf systems: (a) with single rf coil used for both transmission and reception, (b) with separate transmit and receive coils

static magnetic field, usually called B_0). The rf magnetic field, in the presence of field gradients (see *Magnetic Resonance Imaging: A Historical Overview*) manipulates the sample magnetization and nutates (turns) particular portions (i.e. all magnetization in a selected slice or volume) away from the direction of B_0 . Inhomogeneous B_1 can cause undesirable non-uniform nutation in different parts of the sample.

The simplest modulated rf signal is a 'square' pulse, that is, on at a fixed level for some period of time and then off. More complex pulse shaping is often used in MRI to excite the magnetization in selected slices or volumes of the sample. One common example is the 'sinc' function, $\sin(x)/x$, used for slice selection. More sophisticated magnetization can be accomplished by a series of complex pulses.

After the magnetization is prepared in the desired way by one or more rf pulses, the transmission is shut off (usually by the transmitter and the T/R switch) and the receive chain listens for the NMR signal from the precessing nuclei. In the system shown in Figure 1(a) a voltage and current are induced in the single rf coil by precessing nuclei and are first picked up by a *preamplifier* or 'preamp'. The preamp must have a low noise figure, that is, it should add very little noise to the signal coming from the rf coil. The amplified signal from the preamp proceeds through an rf receive amplifier, which further increases the signal strength to a high level. The signal is then fed to a *mixer* which 'mixes' the NMR signal with a local rf frequency oscillator. An 'audio' signal is produced whose frequency is the difference between the local oscillator and NMR frequencies. Audio signal frequencies typically lie in the range 0–100 000 Hz.

The system shown in Figure 1(b) is similar to that in Figure 1(a) except that there are separate transmit and receive rf coils. The rf magnetic field B_1 which causes the spins to nutate is produced by the transmit coil, and the receive coil senses the returning signal from the precessing nuclear magnetization. Examples of this arrangement might be to transmit with a volume coil (i.e. a body coil) and receive with a surface coil.

The audio signal is finally digitized (i.e. turned into numbers representing amplitude as a function of time) and fed into the system computer where it is processed to form an image or spectrum.

3 RF COILS

Two general classes of rf coils are *volume coils* and *surface coils*. Volume coils are constructed to enclose a substantial portion of the body such as the torso, the head, or an extremity. A typical surface coil is a small, simple metal loop which is placed up against the portion of the body to be examined. Generally speaking, volume coils have a large field-of-view but modest S/N, while surface coils have a small (shallow) field of view but better S/N. The *phased array* is an assembly of overlapping surface coils which can have the field-of-view of a volume coil but the S/N of a surface coil.

3.1 Signal and Noise in Rf Coils: S/N

One of the most critical parameters for imaging or spectroscopy is the S/N. The signal comes from precessing nuclear spins and is picked up by the rf coil. Electrical noise generally

takes the form of random excursions of the electrical signal and is associated with thermal fluctuations in electrical resistances of the rf receiving system.

We can examine the sources and characteristics of signal and noise from the schematic model of the NMR receiving electrical circuit shown in Figure 2. The rf coil has an inductance (L_C) and is resonated by capacitors C_1 and C_2 in series. The capacitive divider C_1/C_2 is arranged so that the input/output impedance of the rf coil is approximately 50 Ω . (C_1 and C_2 may be the equivalent of the series or parallel resultant of many capacitors in a real rf coil.)

The electrical losses represented by resistors R_C and R_S correspond to electrical losses in the coil and sample, respectively. Electrical noise in the circuit comes from the resistors. The coil and sample noise voltages corresponding to the resistors are given by the Johnson noise formulas $V_{nC}^2 = 4R_C k T df$ and $V_{nS}^2 = 4R_S k T df$ respectively, where k = Boltzmann's constant, T = temperature in Kelvin and df is the observed bandwidth in Hz. V_{NMR} is the NMR signal voltage.

The NMR voltage, then, is competing with the noise voltages produced by losses in the coil and losses in the sample, so minimizing the losses will minimize the noise.

Another measurement of losses is the ' Q ' of a resonant circuit which can be applied to Figure 2 by the equation $Q = \omega L_C / R$, where R = total resistance. Thus, the higher the Q , the smaller the losses.

The losses in the coil itself can be decreased by making it with a metal conductor with low resistance or, as has been tried recently, high-temperature superconductors.³ However, the sample losses are a function of the relative geometry of the rf coil and sample (or parts of the body, in this case). So a body coil, which wraps around a person, will have a maximum S/N for a voxel of a certain size which can be approached (but never quite reached) by ensuring that $R_C \ll R_S$. This can be defined as the 'intrinsic S/N' for that geometry.⁴

Physically, a voxel of a certain size produces a precessing magnetization which is picked up by the rf coil. The sample (i.e. the human body) has thermally generated circulating currents which are also received by the coil. So the S/N is basically a competition between the NMR signal and the noise produced by the circulating currents.

The sensitivity of an rf coil to a voxel of precessing magnetization is proportional to the rf B_1 magnetic field created at the position of the voxel by unit current flowing in the coil.^{1,5} Whole body and head coils have fairly uniform sensitivities throughout their volumes. They are, however, somewhat distant from voxels of interest, and are therefore relatively insensitive.

Figure 2 Equivalent electrical circuit for rf coil showing inductance of the coil, resonating and matching capacitors C_1 and C_2 , equivalent loss resistors R_C and R_S for losses in the coil and sample, respectively, and noise sources V_{nC} and V_{nS} corresponding to the loss resistors R_C and R_S . Also shown is V_{NMR} , the NMR signal voltage

Since they also contain large portions of the body, the noise picked up from the thermally generated noise currents measured above is relatively large. Surface coils are comparatively close to volumes of interest and see smaller regions of the body, which gives them less noise. As would seem reasonable, therefore, S/Ns in general increase as one goes from body to head to surface coil.

For a voxel at a particular depth inside the body, the best possible S/N can be closely approached by using a circular loop surface coil whose diameter is approximately equal to the depth of the target voxel.^{1,6} (The actual relationship is optimum coil diam. = $0.89 \times$ voxel depth).

Finally, for a given coil and sample geometry, the intrinsic S/N is proportional⁴ to the magnitude of the static magnetic field, B_0 . As the field increases, a larger magnetization is produced proportional to B_0 and the signal for a given magnetization is proportional to the precession frequency which is in turn proportional to B_0 . Thus the net signal is proportional to the product of these factors, or $S \propto B_0^2$. Higher frequencies cause the losses in the thermally generated circulating currents in the body to increase and the noise $N \propto B_0$. The net effect is that the intrinsic $S/N \propto B_0$.

There are two other factors that affect S/N for practical MRI and MRS systems. First, T_1 relaxation times increase slowly as a function of field strength,⁷ which works against the advantage of increasing field for MRI repetitive pulse sequences; this effect is not large, however.

Second, as the field decreases, it becomes more difficult to make rf coils which approach the geometric intrinsic S/N limit, that is, rf coils whose electrical losses are small compared with the losses of rf-induced currents in the body. Generally speaking, systems at $B_0 = 1.5$ T can easily achieve negligible noise contributions from the rf coils, whereas systems with B_0 less than 0.1–0.2 T have substantial noise contributions from rf coils. Superconducting rf coils³ may reduce noise contributions from coils and help low-field systems approach the intrinsic S/N limit. However, at best, such coils can only get to $S/N \propto B_0$, so a 0.1 T system will, in the most favorable case, have an S/N approximately 15 times worse than the S/N for a 1.5 T system.

3.2 High-Frequency Rf Coil Considerations: Distributed Capacitances

There are two important challenges to making large-volume high-frequency rf coils suitable for MRI and MRS of human subjects. The first is to obviate adverse effects of stray capacitance between wires comprising the coil and external conductors or between various parts of the coil itself. The second is to make volume coils having uniform magnetic fields that will therefore provide uniform excitation and reception of magnetization.

We illustrate the stray capacitance problem by considering how to make a large loop work at high frequencies. The problem is that there is capacitive coupling between the loop and its surrounding and between different parts of the loop. Electric fields around the loop tend to divert current through the stray capacitances instead of keeping the currents in the loop, which spoils the coil's operation. In principle, there are two possible ways to mitigate this effect: decrease or control the stray capacitance, or decrease the electric field.

The Faraday screen² is an attempt to control stray capacitance. It is a structure consisting of a collection of wires, usually in a plane, having a common connection but no closed loops. It is supposed to offer a low impedance path for electric fields. It is generally placed between the coil and other conducting structures (i.e. the body) in the hope of preventing coil electric fields from interacting with external objects. Thus stray electric fields tend to return through the Faraday screen and therefore do not produce currents from the coil to external conducting objects.

The Faraday screen is helpful in decreasing the interaction between the rf coil and nearby conducting structures such as gradient windings. However, it does little to solve the problem of currents through coil-to-coil stray capacitance. Second, the wires which comprise the Faraday screen have substantial inductance and therefore do not offer a much lower impedance path than the stray capacitances. So currents through Faraday screens do introduce some electrical loss that can have an observable effect on coil Q , where only extremely low losses can be tolerated.

Using multiple distributed capacitances in the rf coil decreases the electric fields generated by the coil and thereby reduces currents through stray paths. This idea was known to some electrical engineers for specialized antennas,^{2,8} but was not really utilized in the NMR community before the advent of MRI. The problem and solution are illustrated in Figures 3 and 4. Figure 3 shows the application of distributed capacitances to a loop coil (often used as a surface coil). Figure 3(a) uses a single capacitance C to resonate the loop inductance at the desired frequency. The capacitance C is divided in order to provide an impedance match to 50Ω . Figure 3(b) is the same size loop, also resonated with net capacitance C . However, this time the capacitance value C is achieved by putting eight capacitors, each with capacitance $8 \times C$, in series. (The input capacitance is again divided in order to achieve an impedance match).

Distributing capacitances actually decreases the electric fields. Figure 4 is a sketch of radial electric fields around a

Figure 3 Distributing capacitances in an rf coil decrease electric fields and allow operation at high frequencies. (a) Single-loop rf coil whose inductance L is resonated with capacitance C in one location. The capacitance is divided in order to provide an impedance match to 50Ω . (b) Single-loop rf coil with inductance L , also resonated with net capacitance C . However, this time capacitance value C is obtained by putting eight capacitors of value $8 \times C$ in series, physically distributed around the loop

Figure 4 Sketch of radial electric fields around a simple loop surface coil using a single capacitance or multiple capacitances as shown in Figure 3(a) and (b) respectively

simple loop surface coil using a single capacitance or multiple capacitances as shown in Figures 3(a) and (b) respectively. With capacitance concentrated in one part of the loop, the radial electric field for a given current changes around the loop as shown by the single large curve, and varies from -4 to $+4$ in arbitrary units. With distributed capacitances, the electric field change of each section of the conductor (which has inductance) is approximately canceled by the opposite electric field change across the adjacent capacitor. Thus, putting in eight capacitors instead of one in the loop reduces the electric fields available to drive currents through stray paths by about a factor of 8.

3.3 Solenoid, Saddle, and Birdcage Rf Coils

The three most commonly used volume rf coils (Figure 5) are the *solenoid* coil, the *saddle* coil and the *birdcage* coil. The solenoid coil is simply a helical winding on a cylinder which produces a field down its cylindrical axis. It is used when the symmetry axis of the static field is perpendicular to the direction of insertion of the sample, i.e. the patient, because the rf field B_1 has to be perpendicular to the static field B_0 .

Figure 5 Rf coils: (a) solenoid; (b) saddle; (c) birdcage. In MRI, cylindrical symmetry is often important. The solenoid coil produces an rf field down its symmetry axis which must be perpendicular to the static field (B_0) axis. The saddle coil and birdcage coils produce their B_1 field perpendicular to their cylindrical symmetry axis which is aligned with B_0

The saddle coil and the birdcage coil⁹ (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*) both produce rf B_1 fields perpendicular to their cylindrical axis. The birdcage coil is a more sophisticated design and has a higher degree of azimuthal symmetry. A birdcage coil can easily be adapted for quadrature excitation and quadrature reception. Two perpendicular saddle coils would be necessary for quadrature, whereas a solenoid coil would need to be used with a saddle coil in order to get quadrature.

At high frequencies, where most of the electrical losses (and therefore electrical noise) comes from the sample, i.e. the patient, solenoid, saddle, and linearly excited birdcage coils will give about the same S/N. At low fields (and hence low NMR frequencies), electrical loss in the coil can be significant or even dominant compared with electrical loss in the patient. The solenoid coil has less resistance per unit field generated than the saddle or birdcage coils.⁵ So at low frequencies the solenoid coil can offer some S/N advantage over a linearly excited saddle or birdcage coil. Quadrature operation of a birdcage (or double saddle coils) gains back S/N. The exact comparison depends on the particular system and its parameters.

3.4 Homogeneity of the Applied Rf Field and Receive Sensitivity

It is important that the rf magnetic field B_1 applied to the spin sample be uniform in order to get the nutated magnetization consistent over the target volume. Homogeneous excitation is particularly important for complex pulse sequences. These sequences may contain multiple pulses, and relatively small errors can accumulate to produce large magnetization errors at the end of the pulse train. Thus volume coils, which have fairly uniform B_1 , are often used for sample excitation.

Surface coils may be used for the transmit pulse when the homogeneity of excitation is not critical, for example, in spectroscopy, when a single excitation is applied. Pulse sequences containing refocusing (i.e. 180° pulses) usually require more precision and are generally applied with a volume coil.

The B_1 produced at a point in space by a unit current in an rf coil is proportional to the sensitivity of the coil to the NMR signal coming from that point in space.^{1,5} Because volume coils produce a uniform B_1 , they also have fairly uniform sensitivity. The sensitivity of surface coils is strongest near the coil and falls off with distance away from the coil. Surface coil S/N near the sample surface is generally substantially greater than S/N for volume coils. The enhanced surface coil S/N is frequently more important than its nonuniform sensitivity. A common strategy is to use a volume (or other large) coil to produce a uniform excitation and a surface coil for high S/N reception. With this arrangement, however, it is generally necessary to use some sort of electronic *decoupling* of volume and surface coil in order to avoid having the transmitted pulse create currents in the receive coil, which will distort the applied rf B_1 field. One such decoupling scheme uses resonant blocking circuits in the receive coil to block current flow.^{1,2,10}

The only real problem with the surface coil is its limited FOV. The NMR phased array¹¹ is a collection of overlapping surface coils which has the sensitivity of a surface coil and the FOV of a volume coil (see *Whole Body Machines: NMR Phased Array Coil Systems*). Each surface coil requires its

Figure 6 Example of quadrature rf system. During transmit, the quadrature hybrid splits the incident rf power into two equal parts which are 90° out of phase. These outputs are fed to two quadrature ports of the rf coil and produce a circularly polarized rf excitation pulse. During receive, the circularly polarized NMR signal creates signal at the two quadrature ports which are 90° out of phase. These are fed back through the quadrature hybrid which causes them to combine in phase and produce an output at the fourth quad hybrid port. The resulting signal is then sent through the receive chain and processed in the usual way

own receiver chain and the processing is complex. The phased array has so far been used for applications using a few surface coils in the array, such as arrays to study spines, knees, neck, or shoulder. In principle, one- and two-dimensional phased arrays (some of them large) could be used to carry out all imaging and spectroscopy optimally. However, universal application of this technology would require considerable hardware and software development.

3.5 Quadrature

Once the magnetization in a spin system has been nutated away from the static field direction, it precesses around the static field with a circular polarization; that is, the spins precess either clockwise or counterclockwise when viewed along the static field direction. It has long been known^{1,5} that applying a circularly polarized rf excitation could save a factor of 2 in rf energy, and, receiving in a way that is only sensitive to the correct circular polarization, would gain a factor of approximately $\sqrt{2}$ in S/N.

The general idea for quadrature transmit is to apply two linear B_1 excitations at right angles in a plane perpendicular to the static field, B_0 . If the excitations are 90° out of phase, a circularly polarized B_1 results. The angular direction of the circular polarization is determined by the relative phase of the excitations, that is, whether the second excitation is 90° ahead or behind the first. In the language of electrical engineering, we will call the quadrature connections to the coil the quadrature ports.

Quadrature reception is achieved by taking the outputs of the quadrature ports and combining them with the correct 90° phase delay so the signals from the circularly polarized NMR magnetization reinforce.

The birdcage rf coil⁹ (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*) is naturally suited to quadrature excitation and can easily be connected in a quadrature configuration. Other possible quadrature configurations with volume coils are two saddle coils at right angles and a solenoidal coil plus saddle coil. This arrangement requires two coils, one on top of the other, which is inconvenient.

Figure 6 shows an example of a quadrature rf system. The key new element (not found in our earlier system diagrams, Figure 1) is a *quadrature hybrid*.¹ A quadrature hybrid is a symmetrical four-port device with a pair of equivalent ports at the input end and a corresponding pair at the output end. A signal sent into a port at the input is split into two equal parts

at the output; the output signals are 90° out of phase. Such splitting is ideal for quadrature coil operation. During transmit, the rf power excitation pulse is connected to one of the hybrid inputs. The hybrid outputs are fed to the two quadrature ports of the rf coil and produce a circularly polarized rf excitation pulse. During receive, the circularly polarized NMR signal feeds back through the hybrid output ports, which causes them to combine in phase and produce an output at the second input hybrid port. The resulting signal is then sent through the receive chain and processed in the usual way.

A phased array can also make some gain in S/N by combining perpendicular elements of the magnetization signal using weighting that takes the S/N of each component and the circular phase properly into account.¹ However, this enhancement is generally less than the $\sqrt{2}$ improvement in S/N that can be realized in a volume rf coil.

Refrigerated and Superconducting Receiver Coils for Whole Body Magnetic Resonance

Michael Burl and Ian R. Young

The Robert Steiner MRI Unit, Hammersmith Hospital, London, UK

1 INTRODUCTION

Though the potential gains in signal-to-noise ratio for the NMR experiment of refrigerating the detector coils was pointed out some time ago,¹ they have been rarely applied² and then without a sufficiently large gain in performance to persuade machine-users that they should be widely adopted. The use of very cold coils for experiments involving human studies imposes additional constraints. Clearly, the degree of thermal protection needed is much greater and the design of the cryostat to be used is influenced by factors such as the need for it to be tailored to the shape of the body, or be comfortable if the patient has to lie on it.

Whole body experiments differ from most high-resolution experiments in that, at most fields, the dominant noise in the system is derived from the subject's body rather than the detector coils. Where body noise is the major contributor, even reducing coil noise to nothing may not result in significant improvements in signal-to-noise ratio, and the additional technical difficulties added by the necessary cryogenic system seem quite unjustified. It has been considered that cooling is only useful in low-field systems where it can be difficult to reduce coil noise to a level where it is a small fraction of that due to the body.

However, there are circumstances in which it can be predicted that cooling may be useful in machines operating at fields which are quite comfortably in the range normally used for whole body studies, and, with the increasing interest of researchers in the application of MR to interventional investigations and the monitoring of therapy, which are likely to be conducted at lower fields rather than higher for reasons associated with the other facilities needed to perform such procedures, there is the prospect of increasing interest in the investigation of cooled detector coils in whole body studies.

First experiments with whole body systems were conducted using copper coils cooled to liquid nitrogen temperature.³ Subsequently there was little interest in the topic until the development of coils based on high-temperature superconductors (HTSC) such as YBCO ($\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$).⁴

2 BASIC CONCEPTS

Hoult and Richards¹ derived the relationship for the signal-to-noise ratio of the NMR experiment as:

$$S/N = K_A \omega_0^{7/4} T^{-1/2} \rho^{-1/2} \quad (1)$$

where ω_0 is the frequency of the resonance, T is the absolute temperature and ρ is the resistivity of the material of which the detector coil is made. K_A is a constant embracing all the other terms in the relationship. (In this article, only those terms in S/N , and other formulations which are directly relevant to the argument will be identified. All other terms will be included in a series of constants, of which K_A is the first, to be followed by K_B , etc.)

As Hoult and Richards pointed out, equation (1) implied a potential gain of about 2.8 times in signal-to-noise ratio as a copper coil was cooled from ambient to liquid nitrogen temperature. (The direct gain in S/N from the reduction in temperature is augmented by a parallel, though smaller, decrease in resistance of the copper coil.)

The whole body experiment, in which body loading can represent the dominant noise contribution, presents a more complex picture. Hoult and Lauterbur⁵ derived the S/N for a head in this case as having the form:

$$S/N = \frac{K_B \omega_0^2}{(K_C \omega_0^2 T_B + K_D \rho_C \omega_0^{1/2} T_C)^{1/2}} \quad (2)$$

where T_B is the body temperature and T_C that of the coil. ρ_C is the resistivity of the coil. As ω_0 increases, the first term in the denominator grows so large relative to the second that the latter can be ignored.

Refrigerated coils can therefore only be expected to be of significant utility in whole body experiments in three circumstances:

1. At very low fields, where significant body loading of coils is difficult.
2. For very small coils, for studying very localized regions, where coil and preamplifier input noise can again be predominant.
3. For whole body situations where, for clinical reasons, coil loading may be very light. [An example of this might be in pediatric (neonatal) studies in which the coil was designed to surround the incubator containing the very small baby, rather than moving the child from its normal incubator into a special container with a more closely coupled probe with the consequent need to ensure transfer of all the monitoring and life support connections.]

The use of refrigerated coils in high-resolution systems seems to have been very limited² until the advent of HTSC (high-temperature superconductor coils) which has provoked substantial further interest,^{6,7} particularly for microscopy applications.^{8,9} These have been operated at fields of 9–11 T at liquid helium temperature and for small samples.

3 REFRIGERATED CONVENTIONAL METAL COILS

The behavior of refrigerated metal coils is much more predictable than that of HTSC ones (see the next section). The principal metals from which coils might be made (Cu, Al, and Ag) all show falling resistivity as their temperature is reduced, though their rf resistance falls more slowly than does ρ , since the skin depth (δ) is given by,

$$\delta = \sqrt{\frac{2\rho}{\mu_0\omega}} \quad (3)$$

However, the skin depth is still likely to be much less than the mechanical thickness of the metal used in the range of frequencies of interest, even at 4 K. In any form of refrigeration which is likely, it is reasonable to expect that the coolant can most conveniently be handled by making the coil conductor of a tube through which it is passed. Wall thicknesses of 1–2 mm are then reasonable, though more difficult to use in very small coils. This was the method used in the first whole body studies, as shown in Figure 1.

The performance reported in Hall et al.³ using this coil at liquid nitrogen temperature showed a gain of S/N of around 28% in in vivo experiments relative to its operation at room temperature. (The experiments were conducted at 0.15 T). Reducing the temperature toward liquid helium temperature (as in Styles et al.²) can be predicted to show further gains, though these have not yet been demonstrated in vivo, and the reduction in noise obtained in the experiments in Styles et al.² was largely offset by a reduction in filling factor in the high-resolution system used.

The use of refrigerated conventional metals, as against superconductors, does have the advantage of avoiding the impact of the Meissner effect, which can produce local perturbations in B_0 . Since imaging requires a data acquisition bandwidth that is generally quite substantial compared with that of high-resolution studies an excessively high coil Q value has to be reduced as noiselessly as possible. In this context, in any case, it should be remembered that the main benefit for S/N comes from the reduction in T , rather than R [in the noise voltage expression of $(4kTR)^{1/2}$]. In practice, the maximum usable Q value in most experiments can be achieved by refrigerated metal, and, while there are methods of reducing Q without introducing more than small amounts of noise, the gain in performance of superconducting coils may be very small. Note, too, that reducing the source temperature seen by the pre-amplifier may actually cause the noise figure of that unit to be degraded. The limited extent of the potential gains are well illustrated by Figure 2. This shows results obtained by computer

Figure 1 Copper conductor-based surface coil designed to be cooled by liquid nitrogen passed through thin copper tube used to form the probe. (Reproduced by permission of Academic Press from Hall et al.³)

Figure 2 Results of computer modeling of coil behavior, assuming surface coils of one turn (a) and (b), and three turns (c), at an operating frequency of 21 MHz with a body resistivity of $0.85 \Omega \text{ m}$ loading them. The single-turn coil had a diameter of 30 mm, and the three-turn one a mean diameter of 70 mm. Curves (b) and (c) were obtained by modeling at 293 K and curve (a) at 77 K. (Reproduced by permission of Pergamon Press from Penn et al.¹⁰)

modeling for the S/N at various depths for two different coil designs, of one turn and three turns. The performance of the former coil was modeled at room and liquid helium temperatures. Simulation assumed an operating frequency of 21 MHz. The gains obtained are useful, but not startling, as was confirmed by the practical work in Hall et al.³

4 SUPERCONDUCTING DETECTORS

Were it possible to make a noiseless probe system, the filling factor of the sample in it would become irrelevant. In the case of a small sample, the coil would collect signal and sample noise with equal efficiency regardless of its size. In a large sample, with spatial localization, this observation is no longer generally true. As the coil size is increased relative to the object, it detects noise in more of the body while signal collection efficiency is reduced.

Three forms of coil, all using YBCO, have been evaluated as rf probes. Hall et al.⁴ used bulk ceramic rod wound into a helix (Figure 3) and designed to be self-supporting inside its cryostat of thick-walled expanded polyethylene. Black et al.⁸ (for microscopy), and Withers et al.⁷ for whole body imaging, used vacuum-deposited thin films. Hall and his colleagues^{6,10} later went to a thick-film form (Figure 4). This last coil is formed on a Zirconia plate. As was suggested in Hall et al.,⁶ the thick-film coil was less affected by the presence of the magnetic field than the bulk ceramic.

YBCO is a type 2 superconductor with a relatively high critical temperature (T_C) but with a range of transition behavior between its normal conductivity and a complete superconducting state which is a function of its processing and formation. There is an extensive literature on this, but Hojaji et al.'s work¹¹ is typical, showing the variation of properties of one particular YBCO form at varying temperatures. T_C is typically

Figure 3 HTSC YBCO coil fabricated from rod and formed into a spiral. The coil is shown mounted inside its expanded polyethylene cryostat. (Reproduced by permission of Academic Press from Hall et al.⁴)

around 90 K, but the transition in properties is by no means necessarily complete at 77 K (the temperature defined by the boiling point of liquid nitrogen). The material used by Hall et al. in these various studies shows considerable further improvement in its superconducting properties as the temperature is reduced by a further 7–8 K¹² below that of liquid nitrogen. Cooling below 77 K is therefore a potential source of benefit, but substantially less convenient. The consequences are however important as Black et al.⁸ suggest in comparison with Hall et al.⁶ The former reported quality factors (Q) at relatively high field (7 T) of 24 000 at 10 K, while the latter struggled with significant Q variation from a thick-film coil with increasing field in the range 0–0.15 T at 77 K, beginning at 650 and falling to 500. Cooling substantially below 77 K, however, raises the issue as to whether it is desirable to persist with the

use of current HTSC, or to use classic metal superconductors, with the temperature reduced to the order of 4 K. Two-stage refrigerator systems can conveniently reach 20 K or so, avoiding the need for liquid helium, but are quite expensive. Thin-film coils are generally of much better quality than thick-film ones as Withers et al.⁷ report Q values of up to 14 000 at liquid nitrogen temperature at 6.6 MHz. However these coils have to be deposited onto single crystal sapphire or LaAlO_3 wafers. These limit the size of coils to perhaps 5–6 cm in diameter, and are expensive, meaning that large area coverage of the body can be very costly.

The thin-film coils can incorporate their own tuning capacitors as part of the artwork,⁷ and so avoid many of the problems that Hall and his colleagues found with making connections to their thick-film and solid ceramics, and the limitations imposed by the limited Q values of available conventional tuning capacitors of appropriate size and form.

The ultimate limitations on superconducting coil performance are set by an ω^2 -dependent edge noise, and radiation resistance.¹³ The former is significant in materials such as a machined thick-film layer, though small in vacuum-deposited, masked and etched layers. The radiation resistance is essentially a far-field concept, so that it is relevant only to small coils in large systems at higher frequencies. It can be derived using the argument in Hall et al.,¹³ where

$$L = \frac{\mu_0 \pi a^2 N^2}{(8a + 11b)} \quad (4)$$

for an N turn spiral of average radius a and where b is the difference between the inner and outer radius of the coil ($b > 0.2a$). The radiation resistance is given by

$$R_r = \frac{\pi}{b} \sqrt{\frac{\mu_0}{\epsilon_0}} N^2 \left(\frac{\omega a}{c} \right)^4 \quad (5)$$

where c is the velocity of light, and the radiation-limited value of Q by

$$\frac{1}{Q} = 1/6(8a + 11b) \frac{\omega^3 a^2}{c^3} \quad (6)$$

Figure 5 illustrates the approach of cooled conventional and HTSC coils toward this limit. The results suggested that factors such as the dielectric loss angle of the coil substrates are not going to determine ultimate performance. The limiting parameter is likely to be the noise temperature of the preamplifier in practical systems.

5 REFRIGERATION

A key problem in the development of cryogenic coils, regardless of the materials used, is that the gap between subject and detector should not be allowed to grow excessively. In theory, as noted earlier (Section 4), if the detector systems were to be perfectly superconducting filling factors would be irrelevant. With extended objects, far exceeding the region from which useful signal is expected, this is not so. It is important therefore to reduce the gap between the detector and the skin of the subject as far as is practicable.

Figure 4 Thick-film HTSC coil on Zirconia. The Zirconia plate was 100 mm square. The HTSC is approximately 100 μm thick, and is made by forming a film of slurry, fixing it, then machining in the pattern

Figure 5 Approach of cooled copper (77 K) and HTSC coils to the limits set by radiation resistance. Both coils were of three turns and

The problems are, in fact, little different between nitrogen and helium temperatures from the subject's point of view. There should not be physiologically noticeable cooling of the region of the patient due to the coil in, at least, 1 h. Since coils could be used at intervals throughout the day, this means in practice that the insulation must be good enough to last for very long periods without substantial change in the outer temperature of the vessel. In practice only vacuum insulation is good enough to achieve this, while keeping an acceptably small distance between the cool coil and the outside of the cryostat. In this context most coils can be useful in tubular form to provide the passage for the refrigerant, with thermal radiation being the main source of loss. This can be reduced by making surfaces highly reflecting, and the use of layers of Mylar film vacuum-coated with aluminum.

Coils can conveniently be cooled by passing cold gases, rather than cold liquid, through them, so that a reservoir containing boiling liquid can be employed, or some other kind of refrigerator. All transfer lines to and from the coil have obviously to be insulated to the same extent as the coil chamber itself.

Since a cold environment is available preamplifiers (or the first stages of preamplifiers) can also usefully be placed in it. If a metal coil is in use, this can be used as a cold source for the preamplifier (as, for example, in Figure 1), though even just the input stage of the amplifier represents a significant heat load.

6 CONCLUSION

The use of detectors at cryogenic temperatures is of much greater interest in low-field whole body systems than in higher,

as body noise is dominant in all except the lowest fields. It seems likely that the main early applications of refrigerated coils will be for microscopy and other systems involving very small samples.

Michael Burl. b 1946. B.Sc., 1972, Ph.D., Westminster University (formerly PCL), 1976. First involved in NMR on joining EMI in 1977 where responsible for the first radiofrequency systems for the resistive and then a cryogenic imaging machine. Approx. 10 papers and 6 patents related to whole body NMR. Research interests: obtaining better images and spectra in vivo.

Ian R. Young. b 1932. B.Sc., 1954, Ph.D., Aberdeen, 1958. No involvement with NMR until joining EMI in 1976, where charged with leading the engineering group developing first a resistive, then a cryogenic machine, installed at Hammersmith Hospital in 1980-1. Approx. 150 papers and 30 patents in whole body NMR and related aspects. Research interests: obtaining better images and spectra in vivo.

Resistive and Permanent Magnets for Whole Body MRI

Frank Davies

Oxford Magnet Technology Ltd, Witney, Oxfordshire, UK

1 INTRODUCTION: ADVANTAGES OF MAGNET TYPES

Permanent magnets are the simplest source of static magnetic field, at least from the perspective of the user. Once magnetized, they require no further expenditure of energy to sustain a stable magnetic field indefinitely. Yet in many applications the limitations of the materials mean that the preferred choice is some form of electromagnet, either resistive or superconducting. MRI is an application where all three types of magnet have found a role, with each having advantages in different areas.

Superconducting magnets rely on conductors that can support current densities of several hundred amperes per square millimeter but need an expensive cryogenic system to support them and are, therefore, used for high-field applications.¹ The reason for considering resistive or permanent magnets is to avoid the cost and restrictions of magnet geometry that the cryogenic requirements of superconductivity bring. When a low field strength is acceptable, permanent magnets offer extreme reliability, while resistive magnets can achieve large working volumes more cost-effectively for the same field strength, up to about 0.2 T.

From an engineering point of view, magnets that provide fields of sufficient quality (field strength and homogeneity) for NMR experiments require more accurate design and build standards than are generally needed for electromagnetic machines. Unique design and manufacturing methodologies have been evolved in the periods since 1960 for NMR spectroscopy and since 1975 for MRI. However, the methodologies are based on conventional analysis of the physics of magnetic fields as developed in the 19th century.

2 FIELD CREATION

The flux density B in the SI system is measured in tesla (i.e., webers per square meter, Wb m^{-2} , the weber being a unit of flux). The flux density in a material is related to the magnetic field intensity H by a constant characteristic of the material considered, namely, the permeability μ (in Henries per meter, H m^{-1}): $B = \mu H$. Values of measured permeability μ are available for different materials: $\mu = \mu_r \mu_0$, where $\mu_0 = 4\pi \times 10^{-7} \text{ H m}^{-1}$ is the permeability of a vacuum and μ_r is the relative permeability of the material. For air, μ_r is almost one, so a

loose convention is to talk of the magnetic field in the working volume of a magnet in tesla.

2.1 Importance of Current Density

The magnetic field intensity generated by a current I flowing in a circular loop of wire with cross-sectional area A at a position z along the centerline of the loop of radius a [see Figure 1(a)] is given by:

$$H_z = \frac{I}{2} \frac{a^2}{(a^2 + z^2)^{3/2}} = \frac{JA}{2} \frac{a^2}{(a^2 + z^2)^{3/2}} \quad (1)$$

where $J = I/A$ is the current density. If the loop of conductor has resistivity ρ , power will be expended to maintain the current I , where the dissipation of power W is given by:

$$W = 2\pi\rho aJ^2A. \quad (2)$$

For electrical machines in general, the power dissipated in the winding must be removed by appropriate cooling arrangements so that the machine may operate in a stable manner at a constant temperature (with inadequate cooling arrangements,

Figure 1 (a) Field of an elemental loop of current for consideration of B_z along the centerline and at point P in terms of a , z , and r . (b) Magnetic field at point P due to a current element Idl

rising temperature causes an increase in resistivity, which, at constant current density, increases power dissipation, and thermal runaway follows).

There are various possible arrangements for cooling, which usually involve deploying air or forced water circulation, that can be applied to magnets. These have been discussed by Montgomery² in terms of optimizing the design of resistive solenoids. Practical considerations of cooling windings limit continuous (dc) current density magnets to some $2\text{--}10\text{ A mm}^{-2}$ of conductor cross-section, which, in a winding large enough for whole body MRI, sets practical upper field values of $0.2\text{--}0.3\text{ T}$. (Pulse magnets and Bitter magnets can reach much higher current densities, to produce very high fields up to 70 T and 20 T , respectively, but the structural characteristics of these magnets are not suitable for the production of uniform fields.)

2.2 Materials

Ferromagnetic materials, of which permanent magnets are a special class, exhibit very high permeability as a result of the ordering of atomic magnetic moments.³ These arise from the flow of current represented by the spins of the valency electrons in the crystals comprising the material. A ferromagnetic material can be viewed for engineering purposes as an array of microscopic current loops that have a 'fictitious' equivalent current around the surface of the material. However the non-linear relationship between this current and the applied magnetic field makes accurate design a difficult process.

A ferromagnetic material exhibits a characteristic hysteresis curve of magnetization against applied field, examples of which are shown in Figure 2. The materials are classified into 'soft' and 'hard' magnetic materials, determined by the shape of the hysteresis curve. In particular, they are distinguished by the level of reverse field intensity needed to demagnetize the material, known as the coercivity, indicated by the extreme value

of H where the curve crosses the $B=0$ axis. Soft materials, such as low-carbon steel, have coercivities below 1 kA m^{-1} , while hard materials can have values as high as 1 MA m^{-1} . These latter materials retain substantial magnetization even in the presence of strong demagnetizing fields and are consequently more commonly described as permanent magnets.

Soft magnetic materials are of great benefit to the magnet designer in reducing the current, or the amount of permanent magnet material, required to achieve a given field intensity in a defined volume by providing a low reluctance flux return path.

3 MAGNET DESIGN

The dominant issue with magnet design is to achieve uniformity of magnetic field throughout the working volume, which for MRI has been defined by Morris⁴ to be ideally better than the natural proton linewidth, i.e. $20\text{--}50\text{ Hz}$ or $1\text{--}2.5\text{ ppm}$ at an operating frequency of 21 MHz corresponding to 0.5 T . In reality, some relaxation of this requirement is possible, and commercial MRI systems look to provide homogeneity of field at $10\text{--}100\text{ ppm}$ of the central field over the working volume.

The exact physical position of conductors or permanent magnets is important in the magnet structure for achieving field uniformity. Inevitably, engineering tolerances for the construction plays a part in deciding the merits of particular features of a design. However, almost all magnets contain secondary arrays of coils, iron or permanent magnets whose contribution to the iron can be adjusted for fine-tuning.

3.1 Analytical Approach to Magnet Design

Any magnet design involves calculating the field created at points of interest by current sources, whether these are current paths or fictitious equivalent currents of permanent magnets, the latter being taken as magnetic moments. Computer-aided simulations are possible that calculate the field from any arrangement of sources although it is usually desirable to simplify this modeling process by such steps as using two-dimensional rotational symmetry.^{1,5} Hand-calculation of all but the very simplest geometries is extremely laborious and not practical for real designs.

With reference to Figure 1(b), the Biot-Savart relation can be used to define the flux density dB for a current I flowing in an element of conductor at a point P:

$$dB = \frac{\mu I dl \sin \theta}{4\pi r^2} \quad (3)$$

For any continuous path, the contribution of all the elements dl can be summed to derive the total field B at any point.

Considering circular coils means that solenoidal MRI magnets can be modeled accurately, particularly when they are air-cored magnets and the current uniquely specifies the strength of each source. Simple addition of loops by straightforward computing techniques builds up the overall cross-section of each coil. In this approach, it is possible to define a desired field profile and compute the required current for each loop in the array, subsequently applying engineering criteria to limit computed currents to practical values.

Figure 2 Hysteresis curve of magnetization versus applied field for a permanent (or hard) material, and a soft (nonpermanent but high-permeability) material, (e.g., iron). The shearing line for a simple magnetic circuit is also shown

Noncircular sources can be modeled using arrays of current loops to define the equivalent surface current (Figure 3a). When permanent magnets are considered, there is no particular merit in a circular source geometry, and in any case, whatever layout of magnet is envisaged, it must be built from brick size and shape permanent magnetic materials. This latter point arises because of the high temperatures and pressures used in the manufacture of permanent materials necessary to achieve high levels of magnetization. The most important problem in dealing with permanent magnets is in defining the value of the magnetization in each element of the array.

3.2 Magnetic Circuit

The difficulty of allowing the magnetization of each element to be a function of field as this affects the design process can be illustrated by considering a simple magnetic circuit (Figure 3b).⁶ The flux density B_i in the material is related to the field intensity in the material H_i by the ratio of the lengths of the magnetic circuit to the air gap (l_i and l_g , respectively):

$$B_i = -\frac{l_i}{l_g} \mu_0 H_i \quad (4)$$

This demonstrates that as the gap increases relative to the magnetic circuit the available flux will decrease. The behavior of the circuit can be related to the magnetic properties of the ma-

terial under consideration by plotting the demagnetization or shearing line on the (B, H) curve of the material (Figure 2). For the simple magnetic circuit, the volume of magnetic material needed for a given gap flux density B_g is given by

$$V_i = B_g^2 l_g A_g \frac{1}{\mu_0 (-B_i H_i)} \quad (5)$$

This provides the useful rule of thumb that the optimum permanent magnet design is one where the maximum value of $B_i H_i$ is obtained on the demagnetization sector of the (B, H) hysteresis curve. This maximum value is an important characteristic of a permanent magnet material and is expressed as an energy density, commonly in nonstandard units of gauss oersted (1 MGOe = 7.96 kJ m⁻³). Complex magnetic circuits are treated by Abele.⁷

4 COMPUTER-AIDED DESIGN (MORE GENERAL DESIGN METHODS)

4.1 Finite Element Methods

Analytical expressions relating field and magnetic sources have been successful in enabling the design of NMR/MRI magnets. However, since the 1980s, the availability of low-cost computers with large processor and memory capabilities has made possible the more general approach of solving field equations using numerical methods, without recourse to analytical description of the source geometry. This approach has been summarized by Trowbridge.⁸

Considering fields that do not vary with time, the field equations used are (in vector form)

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (\text{Faraday's law}) \quad (6)$$

$$\nabla \times \mathbf{H} = \mathbf{J} \quad (\text{Ampere's law}) \quad (7)$$

where $\mathbf{E}$ is the electric field intensity. The material constituent properties are accounted for, as before, by $\mathbf{B} = \mu \mathbf{H}$, $\mathbf{J} = \rho^{-1} \mathbf{E}$. The expressions we shall use are in terms of potentials, since these avoid difficulties of handling discontinuities in the fields at physical boundaries. Employing the magnetic vector potential, with $\mathbf{B} = \nabla \times \mathbf{A}$, the field equation can be written as

$$\frac{\partial}{\partial x} \left[\frac{1}{\mu} \frac{\partial A_z}{\partial x} \right] + \frac{\partial}{\partial y} \left[\frac{1}{\mu} \frac{\partial A_z}{\partial y} \right] = -J_z \quad (8)$$

This equation is solved numerically by dividing the region in which the field is required into many triangular or rectangular units (for a two-dimensional case) or tetrahedrons or cuboids (for a three-dimensional case). In each unit, or element (see Figure 4), the solution of the equation is assumed to be of the form

$$A_z = \alpha_1 + \alpha_2 x + \alpha_3 y \quad (9)$$

which describes a linear variation of potential between the nodes of the triangular region.

Figure 3 (a) Array of coils, to define an equivalent current surface. (b) Simple magnetic circuit

Figure 4 Field modeling by subdivision of space into finite elements

The field within each element may be defined by the value of the potential at the vertices of the triangular elements. A numerical solution is obtained by solving the equations for the elements simultaneously, which involves setting targets for the matrix of simultaneous equations. One way of doing this is to minimize the energy of the array by using variational methods and trial elemental functions. This is a powerful method for handling the nonlinear material properties because it is relatively straightforward to iterate the solution, with each successive approximation using the previous value of the field as a basis for a new estimate of the level of magnetization.

Although the finite element approach is a systematic way of replacing algebraic equations for field mapping, there are still difficulties of accuracy. These are predominantly associated with designing the mesh of elements, but boundary modeling and representing material properties are associated difficulties.

Commercial software packages are available from a number of suppliers,⁵ with extensive features involving time-dependent solutions (eddy currents) and automatic mesh generation. Other numerical approaches are possible, involving integration over active boundaries that have been divided into a mesh in terms of the magnetic scalar potential.

4.2 Shimming (Focus on Accurate, Special Solutions)

The procedure for obtaining fine control of the field profile is to build weak arrays of magnets that can be controlled in strength independently of the main magnet. Small adjustments to errors in the main field of the magnet can be achieved—either by changing the current strength of elements in the shim array or by changing the position of permanent magnets. In this latter context, ferromagnetic materials that are magnetized in the main field of the magnet are practically useful, and develop high levels of magnetization.

The process of calculating how much shimming material to add, and in which locations, involves sampling the magnetic field at a large number of points in the working volume and then solving the equation $A\mathbf{x} = -\mathbf{B}$, where $\mathbf{B}$ is the array of field errors at the measurement points, $\mathbf{x}$ is the unknown array defining the amount of shim material needed at each possible location, and A is a sensitivity matrix relating the two. In practice the values of $\mathbf{x}$ are constrained to a limited number of discrete values, so a complex optimization algorithm is required to achieve a satisfactory solution.

5 EXAMPLES OF MRI MAGNETS

The low-field limitation of permanent and resistive magnets has traditionally led to them being viewed as low-cost systems of modest performance, which resulted in their playing a minor role in the development and spread of MRI. However the dominance of high-performance superconducting systems has been challenged in the late 1990s by a number of designs that provide a dramatic improvement in the openness and accessibility of the field.

5.1 Resistive Magnets

The major concern with any resistive magnet is the stability of the field. This is directly linked to the stability of the current control system in the power supply but is also dependent on the cooling system, since any change in temperature will result in a sufficiently large change of dimension, through thermal expansion, to disturb the central field.

5.1.1 Air-Cored Solenoids

The very first whole body system used for MRI was an air-cored solenoid and a number of examples were built during the early years. A typical configuration is a four-coil assembly operating at 0.15 T as shown in Figure 5. The exposed structure did not create a very friendly appearance, but at least the open space between the coils was some compensation for the small bore size. Despite this limitation on size, the power dissipation was extremely high, and the systems suffered from relatively poor stability and homogeneity. They were rapidly overtaken by the development of superconducting magnets, and production of these early magnets ceased in 1984.

A small number of air-cored solenoids continue to be manufactured. With better mechanical stability and improvements in power supply technology, they offer a cheap alternative at very low fields.

Figure 5 Air-cored, four-coil resistive magnet

Figure 6 CAD design of a C magnet (a), with field profile predicted by finite element methods compared with measured results (b). (From Binns et al.,⁵ with permission)

5.1.2 Resistive Iron Magnets

The combination of resistive coils and iron yoke has been used for generating and shaping magnetic fields since the magnetic effect of electric currents was first discovered.

An early version of the resistive/iron C magnet was used for particle physics experiments, and the design process using CAD techniques was refined by comparing predicted and measured performance (Figure 6). However, it has only recently been developed to provide a practical MRI system with the advantage of a much greater freedom of choice of system geometry.

The advantages of this system derive from the use of cheap materials and simple processes, with simple coils to generate the field, and iron to guide the magnetic flux and control the shape and homogeneity of the imaging region. The iron yoke makes the magnetic circuit design efficient, unlike the air-cored solenoid, and a large patient gap can be provided with only modest power dissipation and low stray field. The use of iron does, however, result in a relatively heavy system—comparable with permanent magnet designs. Nevertheless, the possibility of extremely open designs, such as the 'C' shape, make this combination attractive.

An MRI system based around a resistive C magnet is shown in Figure 7. A pair of water-cooled coils wound from alumi-

num strip is fitted to the yoke, one around each leg to maintain symmetry. Together they dissipate around 17 kW to generate a central field of 0.2 T. The total weight is around 11 tonnes.

The use of resistive coils rather than permanent magnet material for generating fields has significant advantages during construction and installation, since these can be performed without the hazards presented by a strong magnetic field. They allow the magnet to be shut off rapidly in an emergency, a feature that is not possible in a permanent magnet.

The stability of the magnet is of course controlled by the power supply, which in this case uses a state-of-the-art current sensor to maintain the current stable to 1 part in 10^7 . The sensor employs a fluxgate magnetometer to sense the magnetic field generated by the current flowing in a supply lead. Thermal stability (and hence dimensional stability) is assured by precise temperature control of the coil cooling system.

The pole faces defining the patient space are specially shaped to provide adequate homogeneity of the magnetic field while maximizing the gap and minimizing the pole diameter. The conductivity of iron in these pole regions can result in interactions with pulsed gradient coil fields, and measures have to be taken to reduce the resulting field disturbances. The shimming system is also mounted on the pole faces and uses small permanent magnet tokens to correct for local field errors, though additional resistive coils could also be used.

5.2 Permanent Magnets

Permanent magnets are constructed by preparing blocks of the magnetic material that are magnetized in the appropriate

Figure 7 OPEN VIVA: MRI resistive C magnet. (Photograph courtesy of Siemens AG)

direction before being forced into position in the assembly and glued in place. Although the field stability is good, the materials do exhibit marked sensitivity to temperature; consequently, all practical MRI magnets involve considerable attention to ensuring constant temperature operation.

5.2.1 Ferrite

Early examples of permanent magnets for whole body MRI were based on ferrite building blocks. The most notable examples were supplied by Fonar Corporation but suffered from the disadvantage of being extremely heavy. This was a direct consequence of the low energy density, and the need for an efficient yoke to complete the magnetic circuit. Figure 8 shows some of the designs of permanent magnet in schematic cross-section.

More recent samples have used the so-called 'magic ring' design, usually implemented in octagonal form. This has the advantage of being very efficient magnetically but suffers from the disadvantage of a long fully confined tube for the patient, so having all the disadvantages of a superconducting solenoid with none of its performance advantages. Magnets of this type have been produced by Field Effects and Asahi. Typical performance figures show ± 20 ppm homogeneity on a 36 cm sphere at 0.2 T from a magnet weighing less than 9 tonnes. The

Figure 8 Schematic cross-sections of permanent magnet structures

latest variants of this design feature an elliptical cross-section to accommodate the patient more efficiently.

As with all magnetically efficient designs, the stray field external to the magnet is very small, but the stability of the central magnetic field is very sensitive to temperature. A temperature-control system is frequently necessary, though good thermal insulation may be adequate if the room itself has a reasonable temperature control. Ferrite is an attractive material because of its sintered form, which results in inherently low conductivity. This minimizes problems that can arise from eddy currents induced by rapidly switched gradients.

Shimming of these magnets to yield the optimum homogeneity is relatively straightforward. It can be accomplished by a set of specially shaped low-power resistive coils surrounding the patient aperture, each with its own independently adjustable power supply. An alternative shimming method is adjustment of the permanent magnet material itself, either by mechanical adjustment of the main field-generating blocks or by the addition of small magnetized tokens to reduce the local distortions of the field. Generally, a combination of methods will be employed for maximum performance.

5.2.2 Neodymium-Iron-Boron

The development of this high-energy material, first produced in 1982, has allowed a fresh look at permanent magnets. Although it is relatively much more expensive than ferrite, the fact that it can provide more than 10 times higher energy density means that much less material is needed, allowing magnets of 0.3 T to be built at reasonable cost and weight. Unlike ferrite magnets, where the bulk of the magnetic circuit is built out of the permanent magnet material, the Nd-Fe-B is usually contained in a simple structure, such as thin disks, mounted to a soft iron frame. The usual configuration is an 'H' or 'four-poster' design with two large disks of permanent magnet material mounted just behind the pole-faces.

The most widely used magnet of this type is manufactured by Sumitomo Special Metals (who developed the material) for use in the Hitachi Airis system shown in Figure 9. An unusual feature of this design is that the return path through the iron yoke takes the form of two compact columns that are displaced backwards from the centerline. This provides a more open access for the patient, very similar to the 'C' design, but without sacrificing all of the improvement in mechanical stability that comes from using the 'H' design.

A central field of 0.3 T can be achieved with around 2 tonnes of Nd-Fe-B alloy out of a total weight of about 12 tonnes, depending on the size of the patient gap.

With the permanent magnet material occupying a relatively small part of the structure, the properties of the iron used for the remainder have a significant effect on the system characteristics. Interactions between the pulsed gradient coil fields and the iron in terms of both hysteresis and eddy current effects can become significant, and the usual practices of sintering or laminating the material in the regions of changing fields become important.

The properties of Nd-Fe-B would allow its use in magnets of even higher field, but this is precluded by its relatively high cost. This is partly owing to the cost of the rare-earth raw material and partly owing to the complex processing involved, requiring the alloy to be ground into a powder, pressed to shape in the presence of a magnetic field and then sintered, all

Figure 9 AIRIS II: high-performance premium open MR system. (Photograph courtesy of Hitachi Medical Systems America, Inc.)

in an inert atmosphere. These high costs allow superconducting magnets to be competitive, despite the cost of the cryogenic system. Furthermore, as cryogenic technology develops, especially closed-loop refrigerators that allow magnets to operate without cryogenic liquids, the boundaries of competition between the different technologies are becoming blurred.

Surface and Other Local Coils for In Vivo Studies

James S. Hyde

Medical College of Wisconsin, Milwaukee, WI, USA

1 INTRODUCTION

Radiofrequency (rf) coils for MRI and magnetic resonance spectroscopy (MRS) can be classified as (1) transmit–receive, (2) transmit only, and (3) receive only. Transmit–receive coils are almost always either of the birdcage type,¹ with the axis of the coil parallel to the static magnetic field, or solenoidal,² with the axis transverse to the static field. A transmit–receive switch connects the coil during excitation to an rf power amplifier and during reception to a low noise preamplifier. Transmit–receive coils can be optimized for particular anatomic structures, i.e. whole body, head, knee, fingers, etc. Transmit-only coils are nearly always of the same type as transmit–receive coils, but are seldom optimized to a specific anatomic structure. Typically, they are whole body. Receive-only coils detect the signal produced by a transmit-only coil. Because receive-only and transmit-only coils are tuned to the same frequency, special provision must be made to decouple the receive coil from the transmit coil during excitation. It is also desirable to decouple the transmit coil during reception. This article is concerned with transmit–receive coils for specific applications (i.e. fingers) and with receive-only coils. The presentation is in the context of MRI.

The central principle of local coils is the reciprocity theorem.³ If unit rf current is introduced into a matched local coil that is placed on or around an object of interest, an rf magnetic field is produced in the object. The magnitude of those components of the field that are perpendicular to B_0 at a point in space is a complete and sufficient measurement of the relative sensitivity of that coil when used as a receiver. One speaks of the ‘vector reception field’ in implicit recognition of the reciprocity theorem, when discussing the spatial variation of the sensitivity of a local coil. Figure 1 shows a surface coil placed on a test tank containing 0.1 M saline. A small probe is placed in the tank, as illustrated. Relative performance of a series of coils can be tested on the bench by successively introducing unit current into each matched coil and moving the pickup coil around in space and orientation in order to plot the field. The region of sensitivity (ROS) of each coil can be determined by plotting iso-contours of constant magnitude of the components of the vector reception field that are perpendicular to B_0 . Alternatively, and fully equivalent, current can be introduced into the pickup coil, which then becomes the transmitter. If this coil is rotated to give maximum signal at each point in space, the vector reception field can also be determined, i.e. the magnitude of the induced signal in the surface coil under test as a function of the position and orientation of the small transmit or pickup coil.

Local coils are usually close to match, and noise is generated in an ideal system that is the same as that of a 50 Ω resistor. This noise is called thermal, Brownian, or Joulean—all synonyms. The noise contributed by the preamplifiers is usually included in the thermal noise.

In an ideal scanner, thermal noise would dominate. In our laboratory, we use the term ‘system noise’ to refer to noise from static phantoms that is in excess of thermal noise. There are many causes of system noise. Thermal noise has a normal or Gaussian distribution, whereas system noise does not. In living systems, additional noise is generated by pulsatile motion of blood, displacement of tissues because of pulsatile blood flow, respiratory motion, involuntary tissue pulsations, and, possibly, gross subject motion. This noise has recently been discussed in the context of functional MRI using echo planar imaging (EPI).^{4–6} It is physiological in origin and has been called ‘physiological fluctuations’. It is, in fact, signal rather than noise, since it is spatially encoded in EPI sequences. If physiological noise dominates and is spatially uniform, one would expect the ratio of anatomic signal to physiological noise to be independent of voxel dimensions. There ought to exist a crossover at sufficiently small voxel size where thermal noise dominates, but no experiments have yet been published at this level of detail. In the remainder of this article, it is assumed that thermal noise dominates system and physiological noise, but the reader is cautioned that this may not be true in the real world.

The fundamental equation for the signal-to-noise ratio (S/N) as given by Abragam⁷ is valid for local coils:

$$\psi = \frac{\pi}{f} \left[\frac{1}{2} \eta \left(\frac{\nu}{\Delta\nu} \right) Q \chi_0 \left(\frac{\chi_0 H_0^2 V_s}{kT} \right) \right]^{\frac{1}{2}} \quad (1)$$

where f is a factor that takes into account all additional noise of the apparatus, ν is the rf, $\Delta\nu$ is the receiver bandwidth, Q is the quality factor of the receiver coil, χ_0 is the static susceptibility, H_0 is the static field strength, and V_s is the volume of the sample. The filling factor η is given by the expression:

Figure 1 Bench setup for testing local coil performance

$$\eta = \frac{\int_{\text{sample}} B_1^2 \sin^2 \phi \, dV}{\int_{\text{all space}} B_1^2 \, dV} \quad (2)$$

where B_1 is the rf field produced by unit current in the rf coil, and ϕ is the angle between the static field and the vector reception field. Inclusion of the $\sin^2 \phi$ term is a special feature for surface coils because of the highly curvilinear nature of the vector reception field; ϕ is normally set to 90° in discussions of high-resolution NMR probes.

The extensions of equation (1) by Hoult and Richards are helpful.³ However, these fundamental papers were concerned with high-resolution NMR. The thermal noise generally arises from resistive losses in the rf coil in NMR of organic compounds in solution. In MRI, thermal noise arises from eddy currents associated with ionic conductors in the body. Furthermore, the sample size cannot be conveniently changed in MRI in order to alter the ratio of contributions to thermal noise from the body and the coil. The treatments given by Hoult and Richards³ and Abragam⁷ remain rigorously correct, but not necessarily convenient in considering issues of S/N in an MRI context. For a further discussion of these aspects, see Froncisz et al.⁸

2 SURFACE COIL FUNDAMENTALS

2.1 Dominant Loading

Equation (1) shows a dependence of the S/N on $Q^{\frac{1}{2}}$. The quality factor Q can be defined as:

$$Q = 2\pi\nu \frac{P_0}{K} \quad (3)$$

where P_0 is the incident power, and K is the energy loss per cycle. We can divide the energy loss per cycle into loss in the body because of eddy currents K_{body} , and energy loss in the coil because of coil resistance K_{coil} , and define

$$Q_{\text{body}} = 2 \frac{P_0}{K_{\text{body}}} \quad (4a)$$

$$Q_{\text{coil}} = 2 \frac{P_0}{K_{\text{coil}}} \quad (4b)$$

It follows that

$$\frac{1}{Q} = \frac{1}{Q_{\text{body}}} + \frac{1}{Q_{\text{coil}}} \quad (5)$$

Here Q_{coil} is the quality factor that would be experimentally measured with the coil in free space, Q is experimentally measured with the coil on the body, and Q_{body} is a theoretical quantity to be calculated using equation (5). (Sometimes Q is called Q_L , the loaded Q , because the coil is loaded by the body. This is technically incorrect. In the engineering literature, Q_0 is the Q value in the absence of any coupling to a transmission line and Q_L is the Q value when the coil is matched. For details, see Ginston.⁹ The MRI literature is not consistent on this point.)

For a given coil geometry, Q_{body} is fixed. Since signal goes as $Q^{\frac{1}{2}}$, Q_{coil} should be made as high as possible by careful attention to construction details if $Q_{\text{body}} \gg Q_{\text{coil}}$. Conversely,

if $Q_{\text{body}} \ll Q_{\text{coil}}$ it does not much matter how the coil is built. A general rule of thumb is to strive in coil construction to satisfy the condition that $Q_{\text{body}} < \frac{1}{4}Q_{\text{coil}}$, which would result in a less than 10% loss in S/N relative to a perfect (i.e. superconducting) coil. The general principle is to arrive at dominant loading by the body. Dominant loading becomes easier to achieve as the rf increases and more difficult to achieve as the coil dimensions decrease.

The frequency dependence of Q_{body} is a difficult subject that has not been investigated extensively. The ion mobility is frequency and tissue dependent, as is the complex dielectric constant. It seems unlikely that Maxwell's equations could be solved in any realistic computation for the human body, even if these quantities were known. Actual experimental measurements for every coil geometry at the field strength of interest are required.

Loading by the body also causes shifts in resonant frequency. There are two effects: shifts down in frequency because of radiofrequency electric fields in the body from voltage potentials in the coil, and shifts up in frequency because of inductive properties of the body. Downward shifts can be minimized by use of distributed capacitors, and adjustment of the number of capacitors to cancel frequency shifts is possible.

2.2 Crossovers

Figure 2 shows sensitivity data¹⁰ obtained using the test setup shown in Figure 1. Figure 2(a) shows on-axis sensitivity in free space and Figure 2(b) shows the sensitivity in a 0.1 M saline solution for a series of circular coils of various diameters. Small coils are always better than large coils close to the surface. Quantitatively, one would expect large coils to be better than small coils at great depth, and this is clearly seen in Figure 2(a) for free space. For any pair of coils of different diameter, a crossover exists where the coils have the same sensitivity. This point occurs at the 'crossover' depth. In saline, crossovers are much less pronounced [Figure 2(b)]. A conclusion is that for any imaging problem using a surface coil, one should use the smallest possible coil, noting that fields off-axis fall off more rapidly with small than with large surface coils. We are led to the principal theorem of surface coil usage. One should match the ROS of the coil to the anatomic region of interest (ROI). This theorem is patently valid close to the surface, but seems also, from Figure 2(b), to be true at great depth.

A second class of crossovers exists: the depth at which the surface coil sensitivity equals the sensitivity of a whole volume coil. Estimates of head and whole body sensitivities at 1.5 T are indicated in Figure 2. As a rough guide, surface coils are better than quadrature birdcage coils at depths closer to the surface than 6 cm with a head coil and 8 cm with a body coil.

2.3 Decoupling

Surface coils and transmit coils are resonant circuits tuned to the same frequency and in close proximity. Decoupling of a surface coil from the transmit coil is essential. Electrical breakdown can occur, and skin burns are possible if decoupling is inadequate.

The simplest type of decoupling, conceptually, is called 'geometric'. In early MRI scanners, transmit fields were line-

Figure 2 On-axis sensitivity of one-turn circular coils of various diameters (a) in free space, and (b) using the bench setup shown in Figure 1. Head and body coil sensitivities in (b) are estimates

arly polarized. The first surface coils were planar and oriented such that the lines of magnetic flux from the transmit coil were parallel to the coil surface. That is, with z along the bore, x horizontal, and y vertical, if the transmit field is along x , a geometrically decoupled surface coil must lie in the xz plane.

There remains a possibility for geometric decoupling even with quadrature excitation: planar coils can be placed in the xy plane. However, components of the vector reception field that are parallel to the static field will be MRI inactive. Geometric decoupling is never used alone in modern setups because of risk to the patient. It may, nevertheless, be useful in some circumstances in concert with other decoupling strategies.

Edelstein describes active decoupling circuits and passive decoupling circuits.¹¹ The general idea is to use diodes to detune the receive coil during transmit. The diodes are switched with a voltage pulse from the scanner in active decoupling, and by the rf pulse itself in passive decoupling. Several strategies are possible, but decoupling by pole insertion is the method of choice (see Figure 3). An infinite impedance resonant pole is switched into the receiver coil circuit when the diodes fire, and no current flows in spite of the substantial electromotive force (emf) that occurs because of the transmit field. Active decoupling circuits are favored in most commercial surface coils. Passive decoupling can be more convenient for

academic researchers. For more details on passive decoupling, see Hyde et al.¹² It is noted that with small tip angle sequences, active decoupling is favored over passive.

Decoupling can also be achieved by the use of surface coils that are intrinsically isolated by symmetry from any transmit coil which has a uniform field. Intrinsic isolation involves the

Figure 3 Passive decoupling circuit. During receive, the back-to-back diodes are open and resonance occurs at $\omega^2 L_1 C_1 = 1$. During excitation, the emf in the loop causes the diodes to close. If $L_P = L_1$, an impedance pole occurs at ω , and current no longer flows

use of pairs of surface coil loops organized such that the emf induced in one loop during transmit is equal and opposite to the emf in the other loop, and no current flows.^{8,10} One can say that the mutual inductance between the transmit coil and the intrinsically isolated surface coil is zero. There are a number of symmetries where this condition is satisfied. Intrinsic decoupling was pioneered in the author's laboratory, but is now seldom used except in concert with active or passive decoupling. Research continues into properties of surface coils that have different symmetries, but passive or active decoupling is usually preferred even when using a coil that, in principle, possesses the intrinsic isolation property.

2.4 Coupling

The surface coil must be coupled to a transmission line, and two methods are possible: capacitive and inductive. In either case, the coupler serves to transform the impedance of the coil to that of the transmission line, thereby achieving the 'impedance match' condition.

Capacitive coupling provides a convenient means to introduce a voltage to switch a diode in order to decouple a coil, and is therefore preferred in commercial surface coils when active decoupling is employed.

Inductive coupling¹³ is accomplished by flux linkage between the surface coil and a loop that terminates the transmission line. Since there is no dc pathway to the resonator, either passive decoupling is required or additional wires must be brought to the coil. A particular advantage of inductive coupling is that the surface coil is free floating with respect to the grounds of the scanner and is, therefore, said to be electrically 'balanced' with respect to the patient.

Safety hazards exist because of rf standing waves in the cable connecting the surface coil. Burns have been reported. This cable should be positioned carefully and should never be looped. Use of a balun can reduce this class of problems.

2.5 Tuning and Matching

Whether to tune-and-match or plug-and-go was a hotly debated question in the early days of MRI. It seemed self-evident that the resonant frequency of the coil should correspond precisely with the Larmor frequency, and the impedance match condition should be satisfied in order to achieve best performance. But, this required valuable scanner and technologist time, and it was suggested that use of a surface coil with fixed tune-and-match (i.e. plug-and-go) might be a practical compromise.

This question was addressed experimentally by Hyde et al.,¹⁴ who made provision for remote tuning and matching in order to measure the S/N carefully without touching the coil setup. The conclusion is that the S/N is not very sensitive to match, and is somewhat sensitive to tuning. In fact, we were surprised: plug-and-go coils are an acceptable solution. The improvement in S/N by tuning and matching is modest. Nevertheless, in the author's laboratory, we always tune and match. Requirements for tune-and-match are greater with high Q than low Q coils. For example, a spine coil is very heavily loaded with a Q less than 50; a finger coil may be lightly loaded with a Q of 200. The latter probably should always be tuned and matched.

2.6 Summary of Fundamentals

1. Match the ROI to the ROS. Additionally, one should match the scanner field-of-view (FOV) to the ROI in order to avoid aliasing:

$$\text{FOV} \simeq \text{ROI} \simeq \text{ROS} \quad (6)$$

2. Strive to satisfy the dominant loading condition:

$$Q_{\text{body}} \ll Q_{\text{coil}} \quad (7)$$

3. The crossovers determine coil selection.
4. Tune-and-match when $Q_{\text{body}} > 100$. Check tuning of plug-and-go coils periodically.
5. Consider coupling and decoupling methods carefully, with patient safety in mind.

3 LOCAL COIL CLASSES

A classification system of local coils, namely surface, partial volume, whole volume, intracavity, and coil arrays, was introduced by Kneeland and Hyde,¹⁵ and is adopted here.

3.1 Surface Coils

Simple loops can be either single turn or multiple turn. If the dominant loading condition is satisfied, single-turn loops are preferred because of the more convenient use of distributed capacitors. For surface coils smaller than 2 or 3 cm, the use of multiple-turn coils may be desirable simply to increase the inductance in order to bring capacitive values into the 100 pF range.

The license-plate geometry (Figure 4) is a rectangular configuration used for spine imaging. This figure permits introduction of the concept of the vector reception field of a current segment. Consider first the current segments in the coil shown in Figure 4 that are parallel to the static field B_0 . The lines of flux lie in xy planes and, therefore, are always perpendicular to the static field. On the other hand, the current segments at the ends of the coil are perpendicular to B_0 , and the lines of flux are in yz planes. Positions exist in space where they are parallel to z , and 'black holes' in the image occur at these points. The locus of black holes is seen readily in a sagittal midline slice. They begin at the surface near the wires at each end and curve upward and outward. Black holes restrict the useful ROS of the coil. A current segment parallel to B_0 is more useful than a current segment perpendicular to B_0 . This is because currents in both parallel and perpendicular segments make the same deleterious contribution to Q_{body} , but the z com-

Figure 4 License-plate geometry used for spine imaging

Figure 5 (a) Planar pair and (b) figure-of-eight, with equivalent circuits

ponent of the field associated with a perpendicular element gives no signal.

A surface coil can be placed 'on-edge'. We imagine a square loop with one edge against the body and parallel to B_0 . We have called this configuration 'remote current return' (RCR). It is difficult to achieve the dominant loading condition at 1.5 T, but at very high fields (3–4 T) such configurations may be useful.

The planar pair¹⁰ and figure-of-eight coils (Figure 5) have the same vector reception fields. The equivalent circuits show that the planar pair and figure-of-eight have two loops in parallel and in series, respectively. A map of the vector reception fields is shown in Figure 6. We have found this class of sur-

face coils to be useful in many different imaging problems, including, in particular, as one member of a quadrature surface coil (see below).

The so-called counter rotating current (CRC) coil (Figure 7) introduces a new surface coil concept: that of resonant modes.⁸ As can be seen in Figure 7, the two coaxial loops exhibit a strong mutual inductance that splits the resonant frequency of the mode where both current directions are the same from that of the mode where they are antiparallel. Both modes can be used simultaneously, for example, for ^1H and for ^{31}P spectroscopy, adjusting the separation of the loops and capacitor values as required.

At high fields, the CRC coil works about as well as a surface coil of the same dimensions. The filling factor [equation (2)] is very poor—most of the stored energy is remote from the body. One might think, from equation (1), that the sensitivity would suffer. However, Q_{body} is correspondingly higher and the ηQ product is unchanged [see equation (1)]. The concept of the filling factor is not very useful in MRI surface coil design, so long as the condition of dominant loading is satisfied. CRC coils require dominant loading; they work well at 1.5 T and above, but are less satisfactory at 0.5 T.

3.2 Partial Volume Coils

In this class of coils, the coil geometry is no longer planar, but has a curved surface that conforms more closely to the contours of the body. The fundamental debate in the design of coils of this type is whether to make mechanically rigid coils

Figure 6 Map of vector reception fields of a planar pair coil using the test setup shown in Figure 1. The planes for plots (a) and (c) pass through the midline of the resonator. The plane of plot (b) is 4.5 cm from the surface of the coil [dotted line in (a)] and orthogonal to the midline

Figure 7 Counter rotating current coil, exhibiting two modes: (a) fundamental or low-frequency mode; (b) high-frequency mode. Arrows indicate the relative directions of current flow at some arbitrary moment in time

that conform, for example, to the anatomy of interest of some substantial fraction of the population, or to make flexible coils that conform to essentially everyone. Rigid coils are more rugged and the rf properties do not change; flexible coils have more variable rf properties and tend to experience mechanical failures. Images obtained with flexible coils can be both better and worse than images obtained with a similar rigid coil. To the author's knowledge, no information exists, beyond these rather qualitative comments, which can be used to compare rigid nonplanar coils and flexible coils.

The butterfly coil (Figure 8) has been adapted for cervical spine as well as lumbar and thoracic spine imaging. This coil has a number of free parameters, including individual loop geometry, angle of loops, and separation of loops. These free parameters permit optimization to the anatomy of interest. A cervical spine coil of this type was in commercial production for a time, but it is no longer available. Radiologists in our institution continue to favor it when very high quality images are required in well-defined regions of the cervical spine.

3.3 Whole Volume Coils

The classic whole volume coil is the birdcage (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*). Consider a continuum of current elements parallel to the axis on the surface of a cylinder. If the currents in these elements vary sinusoidally with one full cycle,

Figure 8 Butterfly coil. Parameters ϕ , d , and D can be adjusted to shape the vector reception field. This coil exhibits the property of geometric isolation for the component of the excitation field that is along the x direction, and intrinsic resolution for the y component. The vector reception field is very similar to that of a planar pair with the same value of d and D that is folded by angle ϕ , although the parameter Z does permit some shaping of the field

it has been known for many years that a uniform transverse field will be produced. The breakthrough in Hayes's work was to arrive at a practical way to accomplish this objective at radiofrequencies.¹

A few comments concerning birdcage geometries may serve to supplement the detailed article by Hayes. A Helmholtz pair [Figure 9(a)] consists of two circular loops on an axis with a separation equal to the radius. Theoretically, the rf field is uniform along the axis of the loops. If, instead of circular loops, the loops are rectangular with the long elements parallel to B_0 , a saddle coil is obtained [Figure 9(b)]. Figure 9(c) shows a six-element birdcage coil. No current flows in two of the elements in the linear mode, and the vector reception fields of the coils shown in Figures 9(b) and 9(c) are identical. This progression is illustrated in Figure 9. It is felt that this conceptual similarity of three well-known coil types (Helmholtz pair, saddle, and birdcage) may be instructive. Modern whole volume coils usually are of the birdcage type, because, as the number of current element increases, the uniformity of the field increases.

A possible exception is the one-turn solenoid.² The solenoid must be used with the axis transverse to the static field, which in the usual solenoidal geometry of superconducting magnets limits its use in human imaging to the foot, and, in the awkward arm-above-the-head position, to the hand and wrist. But, for these applications, we have always achieved better image quality using the solenoid than with any quadrature birdcage coil that we have tested. It is noted that the solenoid geometry gives exceptionally uniform rf field distribution.

Figure 9 (a) Helmholtz pair; (b) saddle coil, and (d) six-element birdcage coils

Figure 10 Quadrature endcap transmit-receive birdcage coil used at 3 T. The bandpass design permitted use of more capacitors, which proved helpful at the high field strength

Figure 10 illustrates a type of birdcage coil that has been used in the author's laboratory for functional MRI (fMRI) of the human brain. It is a quadrature, bandpass, endcap transmit-receive coil, and can serve to illustrate a number of the principles presented in this article:

1. The endcap feature increases the filling factor by a factor of 2, assuming that the object of interest is the human brain. This would make no difference in image quality if the condition of dominant loading (see Section 2.1) is satisfied. Its effect is to increase the degree to which this condition is satisfied. Versions have been built at 0.5, 1.5, and 3 T. It is of particular benefit at 0.5 T, of modest benefit at 1.5 T, and probably of negligible benefit at 3 T.
2. By matching the ROI (i.e. the brain) to the ROS, an improvement of sensitivity relative to a conventional quadrature head coil of about $2^{\frac{1}{2}}$ can be achieved.¹⁶ This is because the Q_{body} is increased due to the fact that there is no coupling to the tissues of the lower part of the head and of the neck and shoulders.
3. If the head is progressively removed from the coil, the S/N increases in the portion of the brain that continues to lie within the coil. The improvement in S/N can be as great as a full factor of 2 relative to that achieved with a conventional head coil. The whole volume coil is in the process of becoming a partial volume coil. In the limit, as the head is withdrawn, it seems almost like a surface coil. The distinctions between these three types of local coil is blurred.
4. The crossover in sensitivity between this head coil and any surface coil will lie closer to the surface because of the improved S/N. It is estimated to occur at about 4 cm depth.
5. The coil has been used in the plug-and-go mode, with tune-and-match checkups every few weeks.

3.4 Intracavity Coils

Coils of this type, while building on the principles of local coils, have a number of unique aspects that are discussed in more detail elsewhere (see Related Articles at the end of this article).

3.5 Coil Arrays

It is self-evident that the sample, namely the human body, is quite large and that it should be possible to perform a number of separate experiments simultaneously. All that is required is a number of separate signal channels for rf amplification, detection, and image formation. The feasibility of experiments of this type was suggested by the present author and his colleagues¹⁷ and was first demonstrated by Roemer et al.¹⁸ (see Related Articles at the end of this article).

Opportunities presented by the availability of four parallel channels for signal acquisition, as in the GE Signa scanners, go well beyond the ideas of the earliest papers. Some of these are discussed here.

3.5.1 Quadrature Surface Coils

If a planar pair or figure-of-eight coil is centered over a single-turn loop, the coils exhibit zero mutual inductance, and the vector reception fields are orthogonal on-axis. Dimensions can be adjusted so that these orthogonal fields are also equal in magnitude. This provides the opportunity for quadrature reception, increasing the S/N by $2^{\frac{1}{2}}$ or, alternatively, halving the acquisition time for equivalent S/N.¹⁹ In one study,¹⁹ signals were combined using a hybrid combiner, and a single channel was used. Nearly ideal performance on-axis was achieved, but phases and amplitudes no longer matched off-axis, and use of a hybrid combiner was less than ideal. Independent signal formation and appropriate summation using two channels should overcome this problem. It is noted that quadrature surface coils of the type described here are in commercial production and are widely available.

3.5.2 Multimode Coils

One and the same surface coil can exhibit a number of independent modes that can be tuned to the same frequency (Figure 11).²⁰ In this coil geometry, there are four independent modes, all resonant at the same frequency. Signals were acquired simultaneously and independently from these four modes and combined, after image formation, for optimum S/N. As the number of spokes increases, the number of modes increases, although the depth sensitivity decreases as the order of the modes increases. There is a similarity, conceptually, between the higher order modes of a birdcage coil and those of this multielement planar coil.

3.5.3 Simultaneous Signal Acquisition from a Surface Coil and a Whole Volume Coil

During reception, mutual inductance between a whole volume transmit-only coil and a receive-only surface coil can couple noise from the transmit coil to the receive channel. For this reason, transmit-only coils should be automatically detuned during reception. However, if the transmit coil and the rf coil have zero mutual inductance because of geometric or intrinsic

Figure 11 Multimode surface coil. Inductive coupling is used. Each coupling loop has the same symmetry as that of the corresponding mode

isolation, detuning is not required. We have seen that geometric and intrinsic decoupling methods are not very satisfactory for isolating the coils during transmit because more than 40 dB of isolation is required. For reception, however, 10–20 dB of isolation is sufficient and this is readily obtainable. Thus, we have the possibility of simultaneously receiving and processing a signal from the transmit coil and from an intrinsically isolated surface coil. This idea was suggested several years ago,^{21,22} and recently demonstrated.²³ An improvement in the S/N of $2^{1/2}$ is expected at the crossover. Closer to the surface, the head coil signal modestly improves the S/N in the combined image; at depths greater than the crossover, the reverse is true, and it is the surface coil signal that modestly improves the S/N in the combined image. At all points in space, using the method of weighted sums,^{18,24} image quality is improved.

Parallel acquisition using the head coil and three modes of the multimode surface coil shown in Figure 10 has been reported in a context of MRS. Use of parallel acquisition improves the S/N in in vivo MRS.

3.5.4 Resolution Enhancement

Ra and Rim²⁵ and Carlson²⁶ have independently suggested that the spatial variation of the overlapping vector reception fields from members of a coil array constitutes information that can be used to improve the spatial resolution by suitable post-processing. This is another intriguing opportunity for the use of parallel acquisition technology.

3.5.5 Summary of Coil Arrays

There are two broad classes of applications of coil arrays using parallel acquisition: (1) to achieve a large field-of-view with a low coil sensitivity in order to break the $FOV \approx ROS$ constraint; and (2) to target a number of coils or modes at the same area in order to improve the S/N or spatial resolution. It has been shown that there can be no correlation of thermal noise in the signals from these modes so long as all mutual inductances are sufficiently small.²⁷ However, system noise and physiological noise may cause an apparent noise correlation. These matters are a subject of current investigation.

4 FUTURE TRENDS

In electrical engineering, the lumped-circuit limit of inductance and capacitance changes progressively to the distributed circuit limit of magnetic and electrical field distributions as the rf increases or the characteristic dimensions of the apparatus decrease. Radiofrequency coils in MRI at high field strengths fall between these limits, and lumped- and distributed-circuit vocabularies are used interchangeably, as in this article. Surface coils can be thought of as near-field antenna—a regime where this type of mixed vocabulary has always been appropriate. This intermediate regime has historically received rather little engineering development, which presents opportunities for continued research.

Local coils have, for the most part, been designed in the past in a highly intuitive manner. This is changing in several ways:

1. Network analyzers are now routinely used for detailed characterization of the rf properties of the coil.
2. Efforts to simulate rf field distributions by using Maxwell's equations are underway in several laboratories. Wardenier's earlier paper on the local intensity shift artifact²⁸ is particularly relevant to surface coils. Finite element methods using powerful computers greatly extend the range of possibilities.
3. Use of optimum control theory approaches for numerical optimization of the coil design, which was introduced by Wong et al.,²⁹ seems certain to increase in usage. These authors employed the method of conjugate gradient descent for the design of both gradient and rf coils.

The trade-off between exquisite small FOV images using surface coils and lower quality images using whole volume coils is a difficult one. Pathology can be missed using either approach. Systematically investigating an extended region with surface coils uses valuable scanner time in an inefficient manner. Parallel acquisition strategies offer a number of opportunities for ameliorating this difficult trade-off situation, but substantial coil development efforts are required to take advantage of this opportunity.

Surface Coil NMR: Detection with Inhomogeneous Radiofrequency Field Antennas

Coleen S. Bosch and Joseph J. H. Ackerman

Washington University, St Louis, MO, USA

1 INTRODUCTION

Magnetic resonance antennas characterized by inhomogeneous rf fields ($\mathbf{B}_1$) have been used in a wide variety of biological and medical NMR applications as noninvasive probes of local cellular and molecular environments in intact tissues. Perhaps the simplest inhomogeneous $\mathbf{B}_1$ antenna is the original circular surface coil.¹ This antenna consists of a loop(s) of wire tuned to resonance at the desired NMR frequency and positioned adjacent to the sample of interest. The principal coil axis is aligned perpendicular to the static magnetic field ($\mathbf{B}_0$). In this orientation, NMR signal excitation and/or detection is accomplished over a spatial region local to the coil.

The region of sensitivity of the coil can be fundamentally thought of as determined by the magnetic field lines produced by an idealized unit current flowing in the coil.² The magnetic field lines parallel to the coil axis have the greatest flux density in the plane of the coil. They diverge and become less dense with increasing distance from the coil. This highly inhomogeneous (in both magnitude and phase) rf field defines both the excitation and reception profiles of the coil. The transverse component of the antenna's magnetic field, $(\mathbf{B}_1)_{xy}$, the component orthogonal to $\mathbf{B}_0$, contributes to NMR signal excitation and detection.² The spatial distribution of $(\mathbf{B}_1)_{xy}$ for a circular surface coil lying in the yz plane is illustrated for both the xy and xz planes in Figure 1. When the surface coil is used in the single-coil mode as both the transmit and receive coil, the volume over which signal is acquired experiences a dual dependency on $(\mathbf{B}_1)_{xy}$, further restricting the localized volume, as shown in Figure 2. From Figures 1 and 2 it is apparent why the shape of the sensitive volume of a circular surface coil is often regarded as a hemisphere, with the majority of the signal originating within a depth of approximately one coil radius. While this is a convenient approximation, a more rigorous description of the volume interrogated by the surface coil requires consideration of experimental conditions such as the pulse width, pulse repetition rate, and resonance offset.²⁻⁴

The sensitivity of a receiver coil is quantified in terms of the signal-to-noise ratio achieved for a sample volume element, and is related to the $(\mathbf{B}_1)_{xy}$ experienced at the location of the volume element. Surface coils (or, alternatively, local coils) typically achieve a high signal-to-noise ratio over the interro-

gated volume of the coil. This results from the ability to position the sample region of interest directly within the region of intense $(\mathbf{B}_1)_{xy}$ and, at the same time, to minimize noise contributions from other parts of the sample. Additionally, because of their small size, surface coils generally have much higher $(\mathbf{B}_1)_{xy}$ than do large volume coils.

In spite of the high signal-to-noise ratio and localized signal detection advantages associated with surface coils, the inhomogeneous $(\mathbf{B}_1)_{xy}$ can pose severe technical limitations for in vivo NMR applications. The inhomogeneous $(\mathbf{B}_1)_{xy}$ of surface coils produces excitation and detection signal volumes that do not have well defined boundaries. Additionally, when the surface coil is used for excitation, the wide variation in $(\mathbf{B}_1)_{xy}$ produces a wide distribution of flip angles within the sample. This makes applications requiring constant flip angle spatial distribution more challenging with a surface coil. The intense $(\mathbf{B}_1)_{xy}$ near the coil and curved iso- $(\mathbf{B}_1)_{xy}$ lines can also result in significant signal contamination from unwanted superficial tissues. The use of specialized pulse sequences, static field gradients, and separate transmitter and receiver coils have been applied to surface coil spectroscopy to improve local signal detection and surmount these deleterious effects of the inhomogeneous rf field.

Surface coils have found considerable use in human and animal NMR investigations in vivo, including studies of phosphorus energetics, carbohydrate metabolism, blood flow, and diagnostic clinical imaging. Surface coils have been employed as single- or multi-frequency transmitter and receiver antennas, as well as in conjunction with other coils to optimize signal detection and localization (see *Surface and Other Local Coils for In Vivo Studies*).

2 SHAPING THE INTERROGATED VOLUME OF SURFACE COILS

A variety of techniques and pulse sequences have been developed to define and shape better the localized signal volume achieved with surface coils.⁵ Numerous spectral localization techniques utilize linear $\mathbf{B}_0$ gradients in conjunction with surface coil excitation and detection, or detection alone in the presence of homogeneous excitation, to achieve a high-resolution spectrum over a well localized signal volume. Examples include volume selective excitation (VSE), image selected in vivo spectroscopy (ISIS), depth resolved surface coil spectroscopy (DRESS), stimulated echo acquisition mode (STEAM), and related techniques. These localization methods acquire data from a specific, well defined region within the sensitive volume of the coil by either dephasing unwanted signal contributions from other regions, avoiding direct excitation of unwanted regions, or subsequently subtracting out the unwanted signal in a postacquisition data manipulation. Techniques such as topical magnetic resonance (TMR) and surface spoiling⁶ employ nonlinear $\mathbf{B}_0$ gradients to discriminate against signal contributions from unwanted regions. These techniques eliminate signal contamination by rapidly dephasing the unwanted signal in the presence of highly inhomogeneous local $\mathbf{B}_0$ gradients.

Other techniques have been developed that exploit the natural $(\mathbf{B}_1)_{xy}$ gradients of surface coils to improve signal localization capabilities. Rotating frame imaging and related

Figure 1 Magnitude of calculated $(B_1)_{xy}$ as a function of spatial coordinates for a one-turn circular surface coil lying in the yz plane. The axes are given in units of coil radii. The x axis represents the depth into the sample. The $(B_1)_{xy}$ intensity is normalized relative to a value of 100 at the coil center. Iso-field contours are plotted for (a) the xy plane at $z = 0$, and (b) the xz plane at $y = 0$. (Reproduced by permission of Springer-Verlag from C. S. Bosch and J. J. H. Ackerman, in 'NMR Basic Principles and Progress', ed. P. Diehl, E. Fluck, H. Günther, R. Kosfeld, and J. Seelig, Berlin, 1992, Vol. 27, p. 3)

Figure 2 Calculated signal-amplitude distribution maps for a single pulse from a one-turn circular surface coil (used as both transmit and receive coil) lying in the yz plane. The axes are given in units of coil radii. The x axis represents the depth into the sample. Signal amplitudes are normalized relative to an amplitude of 100 for a 90° flip angle at the coil center. Iso-amplitude contours are plotted for (a) the xy plane at $z = 0$, and (b) the xz plane at $y = 0$. (Reproduced by permission of Springer-Verlag from C. S. Bosch and J. J. H. Ackerman, in 'NMR Basic Principles and Progress', ed. P. Diehl, E. Fluck, H. Günther, R. Kosfeld, and J. Seelig, Berlin, 1992, Vol. 27, p. 3)

methods such as Fourier series windowing (FSW) spatially map the distribution of chemical moieties within the tissue along iso- $(B_1)_{xy}$ contours. Special composite pulses have been used with surface coils that are designed to increase the sensitivity of the NMR response to the inhomogeneities of the rf field.⁷ A family of pulse sequences, called 'depth' pulses, made up of phase-cycled simple or composite pulses, achieve spatial signal discrimination through enhanced sensitivity to regions corresponding to very specific flip angles.⁸ Combining multiple composite pulses or 'depth' pulses accentuates this flip angle selective spatial property. The effect of such pulses can be further enhanced by using separate transmit and receive coils with overlapping sensitive volumes.

In contrast to the above techniques that attempt to sharpen further the localization, other schemes have been proposed to compensate for the inhomogeneous $(B_1)_{xy}$ of surface coils. Phase-cycled composite pulses and amplitude- and frequency/phase-modulated adiabatic pulses have been developed which are insensitive to wide ranges of $(B_1)_{xy}$.^{9,10} Such pulses have been successfully applied with surface coil spectroscopy to provide a more homogeneous excitation profile, thereby increasing sensitivity, improving signal inversion and refocusing capabilities, and enhancing efficiency of water suppression and spectral editing techniques.

The use of a homogeneous $(B_1)_{xy}$ antenna for excitation in the presence of surface coil detection not only produces a single flip angle across the sample (thereby allowing use of pulse sequences demanding homogeneous excitation), but can also allow signal reception from regions deeper within the sample.¹¹ When used as a receiver coil only, the inhomogeneous $(B_1)_{xy}$ of the surface coil defines only the reception profile (Figure 1). This is in contrast to the case of surface-coil transmission and detection in which the interrogated volume is determined by both the excitation and reception profiles (Figure 2). An important application of homogeneous excitation with surface-coil reception has been found in MRI in which optimum signal excitation is combined with the high reception sensitivity and localized detection (field of view) of the surface coil.

3 ENDOGENOUS PROTON SIGNAL DETECTION

The homogeneity of the static magnetic field can be optimized on biological samples most readily through monitoring the ^1H signal arising from tissue water.¹² The B_0 homogeneity shim gradient controls are adjusted to optimize the tissue water ^1H FID profile. In many instances, NMR antennas (including surface coils) that are frequency tuned and impedance matched for a resonance other than that of ^1H can still adequately detect the water signal. This is a consequence of the large ^1H concentration in tissue water (i.e. pure water is 110 M in equivalent ^1H), its ubiquitous distribution in tissue (i.e. most tissues are about 70% water), and the very high NMR sensitivity of the ^1H nuclide (i.e. signal proportional to γ^2). If necessary, sensitivity to the ^1H tissue water signal can be significantly enhanced by remotely tuning and matching the coil circuitry to the ^1H frequency.¹³ Assuming that tissue magnetic susceptibility gradients dominate spectral resolution, the linewidth (in ppm) obtained for the ^1H tissue water signal will reflect the

linewidth (in ppm) that will be obtained for the nuclide of interest.

The ^1H tissue water signal can also be used as both an internal chemical shift reference and an amplitude (i.e. concentration) reference. This is especially useful when there is no suitable internal (endogenous) reference for the nuclide of interest.

In spite of the utility of the endogenous ^1H tissue water signal for the purposes mentioned above, the intense water signal (and, to a lesser degree, the endogenous fat signal) can pose a severe dynamic range problem when attempting to observe ^1H signals from metabolites occurring in low concentrations such as lactate and amino acids. In such situations, water suppression and spectral editing techniques applicable to surface coils are required (see *Water Suppression in Proton MRS of Humans and Animals*).¹⁴

4 MEASUREMENT OF RELAXATION TIMES

Accurate T_1 relaxation times can be determined using surface coils in spite of their inhomogeneous B_1 fields.¹⁵ Both saturation-recovery and inversion-recovery type pulse sequences are applicable as long as three conditions are met. First, the number of spins interrogated should remain invariant over the course of the experiment. This can be a problem if metabolite concentrations are changing with time. Second, each spin or each arbitrarily small voxel of the sample must be consistently prepared in the same initial nonequilibrium state prior to relaxing toward the equilibrium state during variable recovery delay periods. Third, each spin or arbitrarily small voxel of the sample must be consistently interrogated at the end of each relaxation delay period. It is not necessary that all spins or voxels experience the same preparation or interrogation conditions. Spin-lattice relaxation will still result in exponential signal recovery characterized by the true T_1 exponential time constant. Phase cycling of the sampling pulse and receiver can be used to reduce errors caused by unwanted transverse magnetization generated by the imperfect pulses.¹⁶ Pulsed field gradients can also be employed to the same effect. Artifactual transverse magnetization is not generally a problem unless rapid pulse repetition conditions (overall recycle periods less than $3T_2$) are employed. Assuming the T_1 recovery is a first-order rate process, a three-parameter single exponential fit of the recovery curve will provide an accurate estimate of the T_1 relaxation time.

Composite or adiabatic pulses used in place of simple square pulses in surface coil T_1 pulse sequences can achieve a more homogeneous sampling response. While not essential for an accurate estimate of the T_1 time, these pulses do result in improved dynamic range and signal-to-noise ratio. Phase-cycled 'depth' pulses can also be used in place of simple square pulses to enhance signal localization to regions receiving flip angles near 180° and 90° that are ideal (maximized dynamic range) for the inversion-recovery experiment.¹⁷

One important, but often unappreciated, consequence of the inhomogeneous field of surface coils and the resultant distribution of flip angles produced within the sample is a spatially dependent partial saturation of signal intensity when data are collected under rapid (relative to the T_1 of the sample) pulse repetition conditions. Regions near the coil, where the flip

angle is typically greatest, will experience greater magnetization saturation, while regions further from the coil will experience less magnetization saturation, and hence may contribute proportionately more to the total signal.

Accurate T_2 relaxation times are more difficult to obtain with surface coils in the single coil mode since the inhomogeneous rf field precludes spatially consistent repetitious refocusing of the spins using simple square pulses. Spin echo pulse sequences can be employed using surface coils although care must be taken to phase cycle refocusing pulses properly to remove artifacts introduced by imperfect refocusing of the transverse magnetization.¹⁸ A further difficulty relevant to the measurement of T_2 , however, is that the phase cycling enhances signal detection from regions receiving close to the ideal 90° and 180° flip angles.¹⁷ In this respect, the spin echo sequence performs as a type of 'depth' pulse sequence. Multiple refocusing pulses (as in a Carr–Purcell–Meiboom–Gill sequence) increase the discrimination against signals not receiving perfect 180° flip angles, changing the interrogated volume as a function of echo number. The use of plane-rotation adiabatic or other $(B_1)_{xy}$ -insensitive pulses provides a more spatially uniform interrogation which significantly improves the refocusing capabilities of the surface coil.

5 CONCENTRATION DETERMINATION

The ability simultaneously and continuously to observe multiple chemical moieties noninvasively in near-real-time makes NMR spectroscopy highly applicable to studies of evolving metabolism in vivo. Since the NMR frequency domain integrated resonance area (signal amplitude) is directly proportional to the number of spins detected, metabolite levels can be quantified in relative or absolute terms.¹⁹

Certain experimental factors must be considered in any quantitative determination of metabolite levels from NMR data. These include knowledge of the interrogated volume and the flip angle distribution over the volume, calculation of magnetization saturation factors if the spins are not sampled under equilibrium conditions, determination of nuclear Overhauser enhancement in decoupling experiments, and assessment of instrumental stability and rf filter response over multiline spectra. Additionally, if metabolite resonance areas are calibrated against a signal from a different sample, or from a different nuclide, differences in antenna loading, as reflected by changes in the quality factor Q of the coil, for the two comparative measurements must be made. Finally, data analysis techniques such as baseline correction, integration methods, and deconvolution of overlapping resonances can also introduce uncertainty in quantitative measurements.

The use of inhomogeneous $(B_1)_{xy}$ coils for signal excitation and/or detection further complicates quantitative metabolite concentration determination since exact knowledge of the interrogated tissue volume obtained and the signal sensitivity distribution achieved over that volume is difficult to determine. Furthermore, the metabolites being measured are generally characterized by different T_1 relaxation times. When signal collection is obtained under rapid pulse repetition conditions, the spatially and T_1 dependent partial magnetization saturation results in each species with a different T_1 having a different effective interrogated volume (see above).

Relative changes in a given metabolite concentration can be obtained in a straightforward manner using surface coils even under rapid pulse repetition conditions by comparing ratios of peak areas. This assumes the metabolite's T_1 does not change during the experiment. If different metabolites are equivalently or uniformly distributed over the same tissue volume, their relative concentrations can be obtained directly from the ratio of their peak areas if the data are acquired quantitatively. Corrections must be made for differential saturation when T_1 values are different and rapid pulse repetition conditions are used. Determining relative concentrations in this manner avoids the problem of the ill-defined interrogated volume characteristic of surface coils.

Determination of absolute (e.g. molar) metabolite concentrations requires calibration of the integrated resonance area against a signal of known concentration or spin count (moles). If an internal concentration standard exists for the nucleotide of interest, absolute concentrations can easily be determined by comparing the peak areas, again assuming equivalent distribution of species over the interrogated tissue volume and either quantitative acquisition conditions or correction for partial saturation.

In the absence of a suitable internal homonuclear reference species, resonance areas can be referenced to the endogenous tissue water ^1H resonance (or, equivalently, that of the natural abundance deuterium signal).^{20,21} This assumes that the tissue water ^1H signal is invariant over the physiological response(s) being investigated and that the tissue water and the metabolites of interest are equivalently or uniformly distributed over the interrogated volumes. Since the ^1H concentration in tissue water is known, the absolute concentrations of metabolites can be referenced relative to tissue water volume, or relative to tissue mass after determination of tissue water content. Referencing a non- ^1H nucleotide to the ^1H tissue water signal typically requires use of a dual-tuned receiver coil [ensuring equivalent $(B_1)_{xy}$ distributions], correcting for differences in antenna loading for all measurements, and calibration of relative signal amplitudes using standards of known composition at the two frequencies.²¹ An external reference (point sample) fixed relative to the coil such that it consistently experiences the same $(B_1)_{xy}$ field provides a convenient signal to correct for sample loading and to achieve the same flip angle distribution for each measurement.

Metabolite concentrations can also be determined by referencing directly to a fixed external reference signal of known content, the signal response of which has been calibrated relative to a standard solution whose characteristics mimic that of the tissue of interest. This assumes that the signal sensitivity and volume of detection of the coil over the reference and standard sample are equivalent (or correctable) to that over the reference and tissue of interest. Volume localized spectroscopic techniques have utilized fixed external references for absolute quantification of metabolite concentrations from well-delineated sample volumes.

6 APPLICATIONS

Since the early applications of surface coils, many studies have focused on detection of the so called 'high-energy phosphates' via ^{31}P NMR.²² The in vivo phosphorus spectrum is

Figure 3 ^{31}P surface coil spectra of rat (a) brain, (b) leg muscle, and (c) liver obtained in vivo at 80.98 MHz (4.7 T) with a 10 s recycle time and 256 averaged transients. (Data courtesy of S.-K. Song)

composed of rather well resolved resonances, as shown in Figure 3. These resonances consist of α -, β -, and γ -phosphates of adenosine triphosphate (ATP), phosphocreatine (PCr), and inorganic phosphate (Pi). These compounds are important in the regulation of cellular energy metabolism.

The pH of the tissue can be determined from the ^{31}P chemical shift of Pi, a quantity readily measured by surface coil NMR. Under physiologic conditions, the Pi resonance represents the rapid chemical exchange averaged shifts of the mole fraction weighted sum of the acid (H_2PO_4^-) and base (HPO_4^{2-}) phosphate species. The observed chemical shift of Pi (δ_{obs}) and the chemical shifts of the acid and base phosphate forms, combined with the Henderson–Hasselbach representation of the acid–base equilibrium, yields an expression for the chemical shift of Pi as a function of pH:²²

$$\text{pH} = \text{p}K_a + \log_{10} \left(\frac{\delta_{\text{obs}} - \delta_{\text{acid}}}{\delta_{\text{base}} - \delta_{\text{obs}}} \right) \quad (1)$$

Since in most tissues the NMR visible Pi signal originates primarily from intracellular spaces, this provides a powerful means of measuring intracellular pH.

The PCr ^{31}P resonance is insensitive to pH changes in the physiologic range (i.e. $\text{pH} \geq 6.2$), and thus is widely used as the ^{31}P chemical shift reference. However, not all tissues possess high levels of PCr [see, for example, Figure 3(c)]. In its absence the α -ATP resonance can be employed as a chemical shift reference as it also is pH invariant in the physiologic range.

The chemical shifts of the phosphate resonances of ATP are dependent upon the degree of magnesium binding to ATP. The intracellular free Mg^{2+} concentration can be determined from the chemical shifts of ATP and consideration of the appropriate chemical equilibria in a manner similar in concept to the measurement of pH from the Pi shift.²²

Resonances coupled via chemical exchange provide a unique window for probing chemical kinetics under equilibrium or steady-state conditions.²³ Considerable ^{31}P surface coil work has been reported in this area. For example, the PCr and γ -phosphate of ATP resonances are chemical exchange coupled through the creatine kinase (CK) catalyzed equilibrium reaction:

By perturbing the ^{31}P magnetization state of one member of this exchange-coupled pair the state of the other is affected in a time-dependent manner related to the kinetic flux. The rate constant for the reaction can be derived from the magnetization transfer process (see *Magnetization Transfer and Cross Relaxation in Tissue*).

A rather unusual use of magnetization transfer with surface coils has been the suppression of the so called ‘bone hump’ from brain ^{31}P spectra.²⁴ When a surface coil is placed on the head of a subject to examine brain phosphorus metabolites, a very intense broad resonance is detected (primarily) from bone adjacent to the coil (see Figure 3(a)). This resonance can be conveniently suppressed by applying a weak saturating irradiation at one edge of the hump. Efficient communication within the broad resonance envelope allows the saturation to spread rapidly throughout the bandwidth of the hump and effectively suppress this unwanted signal.

The high sensitivity of surface coils has made them useful for following exogenously administered NMR active substrates. Of particular significance to in vivo applications has been the use of ^{13}C - and ^{19}F -labeled substrates.^{25,26} The use of fluorinated compounds offers the advantages of negligible endogenous background signal and a ^{19}F sensitivity almost that of ^1H . Many pharmaceuticals obtain their unusual reactivity by incorporating fluorine near their active sites. These compounds are excellent targets for observation by ^{19}F surface coil NMR. Observation of both ^{13}C and ^{19}F nuclides is often complicated by ^1H coupling. Thus, proton decoupling is often required to simplify spectra and improve the signal-to-noise ratio. Figure 4 shows one application of proton decoupled ^{13}C surface coil NMR used to follow the metabolism of administered ^{13}C -labeled glucose and alanine in rat liver in vivo. A time resolution of 5 min was achieved. Because of the high level of metabolic activity and dependence on glucose and other carbohydrates as energy sources, brain and liver tissue have been the focus of many such surface coil studies.

A rather novel use of surface coils has been in the measurement of tissue perfusion (blood flow) via ^2H NMR in concert with $^2\text{H}_2\text{O}$ employed as a freely diffusible tracer of aqueous space.²⁷ The surface coil is used to track quantitatively the wash-in or wash-out of $^2\text{H}_2\text{O}$ administered in a known controlled fashion. Standard compartmental modeling, developed for use with freely diffusible radioactive tracers, can be readily applied to ^2H NMR kinetic data, yielding tissue perfusion in units of mL-blood/(g-tissue·min). This approach can be combined with concurrent surface coil measurements of tissue metabolism to give blood flow and metabolic assessment from the same tissue site in near-real-time.

Finally, note should be made of the use of surface coils in ^1H imaging. Surface coils provide two important attributes in imaging. The first is high signal-to-noise ratio for tissues near

Figure 4 Proton decoupled ^{13}C spectra of surgically exposed rat liver in vivo representing the time course of hepatic metabolism of (a) $[1-^{13}\text{C}]$ glucose and (b) $[3-^{13}\text{C}]$ alanine. Data were obtained at 90.52 MHz (8.45 T) with 5 min time resolution and 1083 averaged transients. The first spectrum (0–5 min) in each case represents background signal contribution before duodenal injection of 0.67 mmol/100 g body weight glucose plus 0.67 mmol/100 g body weight alanine at 20 min. In (a) half of the glucose administered was $[1-^{13}\text{C}]$ glucose; in (b) the alanine was $[3-^{13}\text{C}]$ alanine. C1 Glc- β , the β anomer of C-1 glucose; C1 Glc- α , the α anomer of C-1 glucose; C1, C-1 glycogen; C2,C5, combined C-2 and C-5 glucose and glycogen; C6, C-6 glucose and glycogen; C3 Ala, C-3 alanine. Chem.*, 1989, **264**, 3930)

the coil. Thus, organs and structures near the surface, such as the spine and eye, can be imaged with substantially higher sensitivity than provided by larger homogeneous B_1 volume coils. The second attribute is a limited or localized field of view. This serves to eliminate aliased signals from structures outside the surface coil's field of view. Artifacts from motion outside the surface coil's field of view are also reduced. These two attributes provide the opportunity to use strong gradient encoding for fine image resolution of near surface structures.

7 SUMMARY

Surface or local coils serve as NMR transmit and/or receive antennas with very high sensitivity for tissues adjacent to the coil structure. This signal sensitivity is generally much higher than that afforded by larger, homogeneous B_1 volume coils. Additionally, because of their small size, surface coils have

low inductance relative to larger volume coils. Thus, they are generally more routine to tune and match using traditional tank circuit approaches. The high sensitivity and robust design characteristics have made surface coils the antenna of choice for a wide range of NMR and MRI applications. The inhomogeneous B_1 characteristics of many surface coil designs limit some applications. However, many strategies (hardware, pulse sequence, and data analysis) have been developed that allow quantitative tissue monitoring with surface coils. These antennas continue to play an important role in basic and clinical magnetic resonance.

1 INTRODUCTION

A small surface coil gives a good MRI (magnetic resonance imaging) or MRS (magnetic resonance spectroscopy) signal-to-noise ratio (S/N) close to the coil for a region whose dimensions are comparable to the size of the coil. A small coil has the drawback, however, that its field-of-view (FOV) is therefore limited. A volume coil, which surrounds a substantial portion of the body such as the torso or head, has a large field-of-view but poorer S/N. The *NMR phased array* collects data simultaneously from a distribution of surface coils (one- or two-dimensional) to achieve the S/N of a surface coil with the FOV of a volume coil.

The present discussion generally focuses on MRI. However, the NMR phased array is equally applicable to providing good S/N over a large FOV for spatially resolved MRS, which is accomplished using imaging techniques.

There are a number of technical difficulties that must be overcome in order to use closely spaced surface coils. There is an electrical interaction, which can be eliminated for adjacent coils by overlapping just the right amount to produce zero mutual inductance. Next-nearest neighbors and more distantly positioned coils can be decoupled by attaching a low-input-impedance preamplifier to one of the resonating capacitors for each surface coil.

The simplest realization of the NMR phased array acquires and processes separate images for each surface coil in the array, and produces a final image that is the optimized weighted sum of the images from all the coils. A further advance convolves a few Fourier coefficients from the Fourier transform of the coil sensitivity profiles with the NMR signal in the time domain, and yields a single, small data set that can be processed into images by straightforward Fourier transformation. While this latter procedure has been proven by computer modeling, a true implementation of the convolution scheme will require the development of sophisticated hardware using dedicated high-speed signal processing electronics.

2 OPTIMUM S/N FOR SURFACE COILS: APERTURE SYNTHESIS

The best S/N for a circular-loop surface coil is obtained when the loop diameter is approximately equal to the voxel depth.^{1,2} (The actual relationship is optimum coil diameter = $0.89 \times$ voxel depth.) This relationship is derived by considering the signal from the target voxel versus the electrical noise from the body as the loop size is varied.

Roemer et al.³ calculated the S/N for arbitrary, abstract current distributions on the body surface, and concluded that the best possible S/N consistent with the laws of electromagnetism (the 'ultimate' S/N) would be achieved by a current distribution that approximates the current in a circular loop. A real circular loop has an S/N over 90% of the ultimate S/N.³ Thus a simple circular loop is a useful building block in trying to maximize the S/N quality of MRI and MRS.

With an array of small coils, it is possible to synthesize a larger coil and achieve the optimum S/N for that larger coil. Roughly speaking, if one wishes to look at a voxel at a depth large compared to one of the coils in the array, the optimum SNR is obtained by adding the signals from a collection of circular loops whose total diameter is approximately equal to the depth of the voxel in question.

3 NMR PHASED ARRAY TECHNIQUES: OVERLAPPING COILS AND LOW-INPUT- IMPEDANCE PREAMPLIFIERS

Figure 1 shows a schematic diagram of a four-element phased array for imaging of the spine that illustrates some technical aspects of the phased array assembly.⁴ The basic difficulty of using an assembly of surface coils is their interactions. If two resonant circuits (i.e., surface coils) tuned to the same frequency are brought close together and have significant mutual inductance, the pair develops two new resonances: one above and one below the desired frequency. There are two steps that can correct this problem. First, as the coils actually overlap and the degree of overlap varies, the sign of the mutual inductance changes. There is an overlap for which the mutual inductance is exactly zero, and both coils can be tuned independently to the same frequency. Thus, in Figure 1, coil 1 and coil 2 are overlapped to have zero mutual inductance, as are the coil pairs 2 and 3, and 3 and 4.

The interaction between next-nearest neighbors, for example, coils 1 and 3, and 2 and 4, in Figure 1, can be alleviated by the electrical circuitry of the preamplifier attached to each coil in the array. If one of the several capacitors that tune each coil (see coil 4 in Figure 1) is shorted out, that coil is no longer resonant at its original frequency and no longer disturbs the operation of other nearby coils at the target frequency. Alternatively, if one of the capacitors were resonated with an inductor then current would be prevented from flowing in the coil, and again that coil would not interfere with its neighbors.

In the phased array of Roemer et al., preamplifiers with low input impedance (a few ohms or less) are connected, in series with an inductor, across one of the capacitors in each coil to receive the NMR signal. The inductance plus series low impedance of the preamplifier resonates the coupling capacitor and

Figure 1 Four-element linear phased array coil for spine imaging. Nearest-neighbor interactions are eliminated by overlap. Next-nearest-neighbor and more distant coil interactions are reduced to negligible levels by connection to low-input-impedance preamplifiers, which, with a series inductor, act as a blocking network

forms a blocking network that decreases currents in the surface coil at the NMR frequency, thereby destroying interactions with other coils in the array. The preamplifier–surface coil combination still works as an efficient, low-noise receiver at the NMR frequency, although a complete explanation of this point is beyond the scope of this article.

4 CONVENTIONAL NMR PHASED ARRAY SYSTEM ARCHITECTURE

Figure 2 shows a conventional system architecture for the NMR phased array that is present commercial practice. Each separate surface coil making up the array has its own receiver chain, consisting of preamplifier, mixers, analog-to-digital converter (A/D), and computer buffer. The signals from each coil are digitized and individually converted into images by a two- or three-dimensional FFT (fast Fourier transform). The individual coil images are then combined to form the final image (see Section 5). The drawback of this arrangement is the large amount of data and consequent data manipulation required if there are more than a few coils in the phased array. Present commercial implementation is limited to simultaneous imaging from four coils.

A more advanced concept, time domain processing of phased array data, which makes coil arrays with many individual coils practical, will be discussed below; realization of that scheme requires a very different system architecture.

5 PHASED ARRAY IMAGE RECONSTRUCTION

The present method of image reconstruction takes images from individual surface coils in the NMR phased array and combines them into a final image using weights that maximize the S/N of the result. In a radar phased array, signals in the antennas composing the array have the same amplitude but differ in phase. An image is produced by adjusting each signal

Figure 2 NMR phased array system architecture for sum-of-squares reconstruction. Each coil in the array has its own receiver chain. The signal from each coil is digitized and FFT-processed. The result is combined to give the final image by adding the sums of squares of the individual signals. All receivers operate from the same local oscillator, and the data on all channels are sampled simultaneously

phase to a common value and then adding the signals constructively. For the NMR phased array, each voxel induces a signal in each coil that varies in both phase and amplitude, depending on the relative location of coil and voxel. Individual coil signals produced by a particular voxel are not of equal quality, so a simple summing of the signals is not adequate.

Intuitively, it is evident from Figure 1 that a voxel above, for example, coil 1, will, in the final image, be mostly composed of the image signal for that voxel from coil 1. Similarly, a voxel above coil 2 will, in the end, be mostly composed of the image signal for that voxel from coil 2. A voxel midway between coil 1 and coil 2 will consist of about half of the image signal from coil 1 and half the image signal from coil 2, with a small amount of additional information from other coils. The image intensity of the i th pixel would, in general, be given by^{4,5}

$$I(i) = \sum_j w(i,j)S(i,j) \quad (1)$$

where $S(i,j)$ includes the phase and magnitude of the signal in coil j due to pixel i , and $w(i,j)$ is the weighting factor needed to compensate for the phase and magnitude differences between coils.

If all coils in the array are exactly the same, and have the same gain in their receiver chains and the same amount of noise from the body, the signal magnitude $S(i,j)$ is a good measure of signal quality and can be used as the weighting factor $w(i,j)$. Hence, to a good approximation, the best S/N for the final image is obtained if the image intensity $I(i)$ at pixel i is given by^{4,5}

$$I(i) = \left[\sum_j S(i,j)^2 \right]^{1/2} \quad (2)$$

where the square root is taken in order to restore the appropriate image contrast. This method of combining the images is called ‘sum of squares’, and is shown at the combining ‘+’ in Figure 2. For arrays with different coil sizes and receiver chain gains, the inverse of the noise variance for each coil must be included in $w(i,j)$ in order to give the correct statistical weighting. Equation (2) becomes

$$I(i) = K \left[\sum_j \frac{S(i,j)^2}{\langle N(j)^2 \rangle} \right]^{1/2} \quad (3)$$

where $\langle N(j)^2 \rangle$ is a time average of the square of the noise at the output of the receiver chain for coil j , and K adjusts the dynamic range of the displayed image. The technique using equation (3) is known as the ‘sum-of-squares’ method, and is presently used in commercial phased arrays because it requires no prior knowledge of coil location or sensitivity and hence is easy to use. A drawback is that image artifacts (e.g., wrap-around signal) may give false weights.

The above equations produce an image that retains the strong intensity variations characteristic of surface coil imaging: the image intensity decreases for objects farther from the coils.

The weighting can also be determined using the ‘reciprocity principle’.⁶ The signal $S(i,j)$ in each coil is proportional to a coil sensitivity factor times the nuclear magnetization $M(i)$,

which contains the clinically relevant information. According to reciprocity, the sensitivity of coil j to the magnetization contained in a given voxel i is proportional to the magnitude of the magnetic field $B_1(i,j)$ that would be produced at voxel i by unit current in coil j . Since the spins are only sensitive to rf fields perpendicular to the static field, the component of the calculated $B_1(i,j)$ perpendicular to the static magnetic field must be used.

A combined image without the surface coil variations in intensity can be constructed from a weighted average of each coil’s estimate of $M(i)$, which is proportional to $S(i,j)/B_1(i,j)$. The appropriate weighting factor for each $M(i)$ is the inverse noise variance scaled by the relative signal strength, which is proportional to $B(i,j)$. After cancellation of some of the factors of $B_1(i,j)$, the intensity corrected image is calculated as

$$I(i) = \frac{\sum_j S(i,j)B_1(i,j)/\langle N(j)^2 \rangle}{\sum_j B_1(i,j)^2/\langle N(j)^2 \rangle} \quad (4)$$

where the sum in the denominator normalizes the total weighting to unity. Figure 3 shows a system architecture for B_1 field-map weighting phased array image reconstruction.

The B_1 weighting in equation (4) requires detailed knowledge of the location of the rf coils and a stored array of calculated weights $B_1(i,j)$, and is harder to implement than the sum-of-squares method. Unlike the sum-of-squares method, B_1 weighting is not subject to wraparound artifacts.

The sum-of-squares method [equation (2) and (3)] does not achieve the highest possible S/N for a given reconstruction because the use of signal magnitudes does not produce the optimum combination of signals when the S/N is low or noise is correlated between coils. An additional refinement using the correct phase relationships makes the final expressions somewhat more complicated.^{4,5} To take correlated noise fully into account, the optimum reconstruction would combine signals with a phase angle dependent on the amount of noise correlated in-phase and 90° out of phase with the NMR signal. In practice, the small gain in S/N, typically less⁴ than 10%, is not worth the added complexity in keeping track of the coil positions.

Figure 3 NMR phased array system architecture for field-map weighting reconstruction. Each coil in the array has its own receiver chain. The signal from each coil is digitized and FFT-processed. The result is combined to give the final image by dividing the image strength for a given voxel from a particular coil by the sensitivity of that coil to the voxel position. The sensitivity is proportional to the field strength at the voxel position caused by a unit current in the coil

Figure 4 Four sagittal images taken with a four-element linear phased array coil shown schematically in Figure 1. The four coils receive data simultaneously. The FOV is 48 cm, with a 512×512 pixel resolution, $NEX = 2$, 5 mm slice, $TR = 400$ ms, $TE = 20$ ms, imaging time = 6 min 50 s, and $B = 1.5$ T. Phase encoding is vertical. Only the central 256 points in the horizontal direction are shown. Artifacts at the top and bottom of the images are caused by wraparound

Figures 4 and 5 show the initial images from a four-element spine phased array combined into a final image. In this case, the final image (Figure 5) has also been corrected for nonuniform sensitivity of the surface coils. Areas with low signal (and poor S/N) have been boosted so that all regions have approximately the same signal level. The noise levels in these

regions are also increased, so areas that started with weak signals still have the same (poor) S/N.

6 NOISE CORRELATIONS AMONG SURFACE COILS IN THE NMR PHASED ARRAY

The NMR phased array receives both NMR signals and electrical noise from the imaging subject. The latter is the result of thermally generated noise currents in the subject that produce fluctuating rf magnetic fields picked up by the array. Thermally generated noise in the electrical components of the phased array system also contributes to noise in the final signal and resultant image or spectrum.

Noise generated by the subject can be received simultaneously by several coils in the array, which may produce noise correlations among the coils. The relative amount of correlated noise in two coils depends on the proximity of the coils—the closer the coils, the greater the correlation.

Although noise is one of the most difficult and fascinating theoretical aspects of the NMR phased array system, the practical effects of noise correlation are minor. The amount of correlated noise is sufficiently small that it cannot be used to reduce noise significantly in the reconstructed image or spectrum. Roemer et al.⁴ show that, for a typical case such as adjacent overlapped coils in a spine array, the correlated noise power is calculated to be a maximum of 41%, assuming a dissipative, infinite half-space. The measured correlated noise power was 23%, because the body is finite.⁴ After accounting for the uncorrelated noise in a preamplifier and receiver components and performing the optimum reconstruction, less than a 10% improvement in S/N could be realized by using knowledge of these correlations.

Figure 5 Image obtained by combining the images shown in Figure 4. Regions with weak signals have had their image intensity boosted so that the signal levels are approximately constant over the image. Areas with very poor S/N have been suppressed. The S/N gets worse away from the spine

7 CLINICAL APPLICATIONS

A variety of phased array coil geometries have been used for clinical applications. The improved S/N obtained with the phased array has enabled established diagnostic procedures to be performed faster and/or with higher spatial resolution, and has made possible new procedures that were not practical with conventional coils.

Clinical phased arrays can be classified by configuration into surface coil arrays and volume arrays. The surface coil array is usually a linear chain of coils, and is best suited to observe a superficial structure whose length is greater than its depth. The coils of a volume array attempt to examine all the internal structures of the body part they circumscribe.

The spinal phased array is a prime example of a surface coil array used to improve an established MRI application. Spine imaging with conventional surface coils has been a time-consuming endeavor, because conventional coils have to be repositioned and the scan repeated for several locations along the spine.⁷ The spinal phased array allows the acquisition of a 40–45 cm linear field-of-view in a single imaging period. Using 512×256 pixel resolution on a rectangular field-of-view can yield high-resolution sagittal images. One commercial spinal phased array design is made up of six coils spaced 12 cm apart along the spine. Three choices of four contiguous coils can be activated to image the cervical, thoracic, or lumbar spines. Phased array techniques reduce total examination time for spinal studies by a factor of two or more, and lead to greater patient acceptance and scanning efficiency.⁷

Volume phased arrays were first applied to pelvic imaging⁸ because it was assumed that improved resolution was only meaningful where respiratory motion was minimal. As an alternative to the more traditional volume imaging coils such as the birdcage resonator (see *Birdcage Resonators: Highly Homogeneous Radiofrequency Coils for Magnetic Resonance*), the volume phased array offers several advantages. First, the individual coils of the array can be tailored to fit the anatomy with fewer constraints than are needed for a standard volume coil. Therefore the array can provide a tighter coupling to the signal from the region of interest and can exclude noise from more distant tissue. Second, the array that circumscribes the volume of interest incorporates the benefits of quadrature reception without needing to satisfy the usual requirements of field orthogonality and mode isolation for a traditional quadrature coil.⁵ Finally, superficial regions yield the high S/N of an individual surface coil, whereas the central region has the S/N resulting from averaging signals of the four coils forming the array. The S/N at the center is no better than that of a small quadrature volume coil that has the same overall dimensions as the array. Motion of subcutaneous fat can produce disproportionately larger motion artifacts from the surface array because of tight coupling to the array.

A four-coil pelvic array comprises two coils placed anteriorly and two posteriorly. The S/N for the pelvic array is approximately three times higher than the S/N for a full-sized body coil imaging the same region.⁹ Such an S/N increase permits pelvic imaging with smaller fields-of-view (16 cm), thinner slices (3 mm), and/or higher resolution (512×512).

Phased arrays also facilitate the use of FSE (fast spin echo) techniques to obtain T_2 -weighted images. Long effective echo times provide good contrast in pelvic structures, but at reduced

signal strength. The enhanced S/N of the phased array permits good images to be acquired in a practical scan time using FSE.¹⁰

High-speed imaging sequences using low-flip-angle excitation and gradient-recalled echoes can produce images in about 1 s. Such images taken with a body coil have marginally useful S/N. With the volume phased array, low-flip-angle, gradient-recalled echo sequences can produce clinically useful, motion-free images of the liver¹¹ and pulmonary vasculature¹² during a single breath-hold.

High-resolution images of brain structures can be acquired by applying a volume phased array to the head.¹³ The head array consists of two pairs of coils that cover about 16 cm of the circumference on each side of the head. When studying temporal lobe epilepsy, the coils are placed over both hippocampi, which lie about 5–6 cm from the lateral scalp surfaces in adults. At this depth, the S/N is about 1.67 times better than that of the standard quadrature head coil. Figure 6 is an example of a T_2 -weighted fast spin echo image acquired for a 512×512 matrix on a 3 mm thick slice. The $0.3 \text{ mm} \times 0.3 \text{ mm}$ in-plane resolution is degraded by pulsatile motion of the brain tissue unless flow compensation and cardiac gating are used with the pulse sequence.

MR neurography is an example of a new MR diagnostic technique whose development depends on the S/N advantages of phased arrays. MR neurography¹⁴ employs pulse sequences tailored to highlight peripheral nerves and suppress signals from surrounding tissue such as fat, vessels, and muscle. Inflamed nerves appear hyperintense compared with normal nerves. Because the resulting signals are weak, a high S/N performance is required from the coil array in order to distinguish the nerve structures from the surrounding tissue.

A linear surface coil array has been built to track the brachial plexus, which runs from the neck to the axilla. The brachial plexus is a complex network of four cervical and one thoracic nerves that fuse, mix, and split into nerves supplying the arm, shoulder, and chest. The brachial plexus array has six

Figure 6 Portion of a high-resolution oblique coronal brain image, showing the internal architecture of the hippocampi (the almond-shaped structures indicated by the arrowheads)

coils contoured fit with one coil anterior to each axilla and each clavicle, and a lateral pair covering the volume of the lower neck. The three coils on one side plus the opposite neck coil are activated for a unilateral study. Selecting the middle four coils can give a bilateral study of the central region. The tight coupling of the array to the region of interest produces S/N not possible with conventional coils.

8 REAL-TIME PROCESSING

Real-time data processing techniques, similar to those used for radar and ultrasound, have been developed for NMR signals from the multiple receivers in the NMR phased array.¹⁵ This approach has not been implemented on commercial imagers, since they have relatively few receive channels and since there is not presently a great demand for real-time imaging. As methods of building phased arrays with larger numbers of coils develop and the applications of fast imaging expand, the increased amount of data may make real-time processing attractive.

To see how a real-time processing method is implemented, we need only look at equation (4) and construct a mathematically equivalent expression in the time domain. According to equation (4), the reconstructed image from each coil is multiplied pixel-by-pixel with the associated field map from the rf coil. The results from each channel are then added together. The multiplication function in the image domain corresponds to convolution in the time domain. Hence the NMR signal from each receiver can be convolved with an appropriately designed filter, the results of which are added to form a composite time domain signal.

Figure 7 is a schematic diagram of a real-time processing system. The information from each coil is processed by its associated filter, and the results from all coils are combined into an array in memory as shown. The contents of the memory are then processed by a single FFT. This arrangement differs from that shown in Figure 2 where the data from each coil must be

Figure 7 NMR phased array system architecture for time domain filtered reconstruction. Each coil in the array has its own receiver chain. The signal from each coil is digitized, multiplied by a filter kernel, and combined in a data array with signals from other array coils. The data array is FFTd to give the final image. So only one FFT needs to be done in this case, no matter how many individual coils in the array, in contrast with one FFT per coil in the conventional system (Figures 2 and 3)

FFT-processed. The point is that the FFT is generally done in an array processor, which is relatively expensive. For a coil assembly consisting of a few surface coils, the FFTs of the coils can be done sequentially. For a coil assembly containing many coils, sequential FFTs would impose a significant time penalty. So the present scheme allows the processing of data from many coils in a short time.

The remaining difficulty is the filters, which, at least conceptually, are straightforward. They represent the Fourier transform of the field map generated by each coil. A substantial practical simplification results when one realizes that the coil field map is slowly varying in the image space and needs relatively few terms to describe it properly in the time domain. With this simplification, a practical implementation of the time domain processing uses a filter kernel derived by Fourier transforming the field map and truncating the result. It would be implemented by the application of programmed high-speed signal processing integrated circuits, which would multiply the incoming signal by the appropriate filter function and then combine into an array in memory. These methods are discussed in detail by Roemer.¹⁵

Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems

G. Neil Holland

Erbtec Engineering, Boulder, CO, USA

1 INTRODUCTION

In a magnetic resonance (MR) imaging system, the spectrometer acts as the transmitter of radiofrequency (rf) waveforms and the receiver of the MR signal. Although MR was traditionally implemented by analog circuits,¹ advances in digital circuits have enabled rf transceivers in MR systems to be designed with digital devices for performing those functions previously implemented with analog circuitry.² As with the compact disk player and digital cellular telephone, when used in a spectrometer for MR imaging, digital technology can provide improvements in clarity and fidelity, since digital circuits are not subject to the imprecision and temporal drift inherent in analog equipment.

Implementation of spectrometer functions using digital electronics can provide benefits in the speed and precision of performing frequency shifts for multislice excitation and presaturation pulses, can give improved fidelity and linearity of the transmitted signal waveform resulting in improved slice profiles, can provide precise splitting of the received signal into real and imaginary parts, thus avoiding 'quadrature ghosts', and can give improved filtering for the prevention of aliasing or 'wraparound' artifacts. In addition, the digital spectrometer lends itself to being configured as a multichannel system, and thus is particularly important for implementation of phased array multiple receive coil technology.

2 MR TRANSMITTER AND RECEIVER

2.1 Transmitter

The transmitter forms the rf pulses required for imaging sequences. These rf pulses are fed to an rf power amplifier and ultimately the rf transmitter coil to excite the spin system and to generate a resonance signal. Slice-section techniques use spectrally tailored rf pulses for selective excitation, which is achieved by amplitude modulation of the transmitted rf pulse. The phase of the rf pulses is computer-controlled, and is used in artifact rejection schemes or advanced excitation schemes. To excite multiple slices, the transmitted rf pulse must vary in frequency for each excitation. Consequently, four forms of modulation of the rf carrier are used in MR imaging sequences: pulse, frequency, amplitude, and phase.

In a conventional transmitter, the rf frequencies are generated from a frequency synthesizer controlled by the system computer. Generally, two or more frequencies are mixed, whether in single or multiple stages, by devices known as double balanced mixers to form the final output frequency. Amplitude and phase modulation may also be accomplished with double balanced mixers. For amplitude modulation, the audiofrequency modulation envelope (or pulse shape) is fed as an analog waveform to one input of the mixer and fixed rf level (the 'carrier') to the other input. The modulation envelope is derived from a computerized waveform through a digital-to-analog converter (DAC).

On the transmitter side, several important performance parameters can affect image quality. The first of these, known as 'carrier feedthrough', is in the amplitude modulation section. All mixers have some signal leakage (carrier feedthrough) from input to output, which means that when an amplitude of zero is programmed, the modulator output is not truly zero. This small residual signal affects the quality of the rf pulses, particularly at lower modulation levels (such as for low-flip-angle sequences), and can affect slice profile. In addition, most imaging pulse sequences use a scheme in which the phase of successive rf pulses is alternated. Phase alternation works in conjunction with the data acquisition process to remove artifacts. This requires an exact balance between the 0° and 180° rf phases. Carrier feedthrough can contribute to phase imbalance, as can amplitude imbalance due to dc offset on the DAC that provides the audiofrequency modulation envelope. The exact manifestation of artifacts caused by carrier feedthrough and the complexity of design required to avoid them depend on the detailed implementation of the transmitter mixing scheme. However, the principal advantage of the digital implementation is that modulation artifacts of this form are eliminated entirely.

2.1.1 Digital Transmitter Implementation

A description of a typical digital transmitter is given below, and is illustrated in Figure 1. The major digital building block for this device is known as a numerically controlled oscillator (NCO), or as a direct digital synthesizer (DDS). This device is essentially a single chip frequency synthesizer, which can be interfaced to and controlled by the pulse programmer or host computer, and is set to produce an intermediate frequency (IF) (e.g., 3.5 MHz) via a DAC, which is mixed with a fixed frequency (e.g., 60 MHz) to generate the final output frequency (e.g., 63.5 MHz). The NCO architecture digitally divides the phase of a highly accurate clock by a digital tuning word (typically 32 bits) and uses a look-up table to convert the phase information to the desired frequency and sine wave output format. Structurally, the output of the NCO feeds a digital multiplier, which is used to perform amplitude modulation of the rf pulse. This is achieved by feeding one port of the multiplier with the digital modulation envelope while the frequency data stream from the NCO feeds the other port of the multiplier. Note that with higher levels of digital integration now being achieved, the modulation may be internal to the NCO chip. In addition, the NCO has a phase port that allows coherent control of the phase of the output frequency. Consequently, all four forms of modulation referred to above can be accomplished with a single large-scale integrated (LSI) circuit. Not only does this significantly reduce parts count, and

Figure 1 Digital transmitter representation showing the direct digital synthesis of the output frequency and digital modulation of the rf waveform. Depending on the final required Larmor frequency, an additional mixing step may or may not be required

hence increase reliability, but the implementation also overcomes limitations of the analog design described earlier—basically, by avoiding the generation of the Larmor frequency during the time a zero profile is selected. In both the digital and analog implementations of the transmitter, the final output frequency is generated by mixing the modulated IF to the final output frequency. Although it is possible to get NCO devices that operate at frequencies as high as those used with MRI systems—thus, at least in principle, meaning that an MRI transmitter can be constructed from a single digital device—the output DAC cannot be greater than 8 bits owing to speed requirements, which places limitations on modulation accuracy and hence the quality of the resultant slice profile. The effect of DAC accuracy or number of bits on slice profile has been studied.³ Evaluating the transverse magnetization profile following a small-tip-angle pulse shows that beyond 6 bits, the magnitude of unwanted signal is less than 1%. However, the DAC is also used to set the amplitude of the rf pulse for rf calibration, and must handle the range of tip angles from 180° to as low as approximately 10° for pulse sequences. This means about 5 bits of ‘headroom’ are required, thus meaning that an 11-bit converter would be recommended. The limiting factor in modulation accuracy is not, in fact, the word depth or number of bits used but rather the ‘glitch’ energy of the output DAC. Typically, this results in the loss of another bit of resolution, meaning that in practice a 12-bit DAC is required for rf pulse modulation.

2.2 Receiver

The receiver in an NMR spectrometer or MR imaging system takes the incoming NMR signal from the preamplifier and presents it to the computer system for data processing by FFT. The signal is preprocessed in the receiver to remove the rf carrier in a process known as demodulation or phase-sensitive detection, and split into phase quadrature. This is accomplished by splitting the incoming signal into two identical channels. The signals feed the rf ports of identical double balanced mixers. The mixer local oscillator (LO) ports are fed with reference frequencies at the same center frequency as the input

signals, but the phase of the two reference signals differs by 90° . In a conventional receiver, programmable audiofrequency low-pass filters (usually Butterworth) operate on the quadrature signals to remove unwanted upper sidebands and to improve the signal-to-noise ratio (S/N) by matching the bandwidth of the filters to the known bandwidth of the NMR signal. After the filters, the quadrature NMR signals are digitized by a pair of analog-to-digital converters (ADCs). The conversion rate of the ADCs is determined by the bandwidth of the NMR signal. Typically, twofold oversampling is used. For example, for a 256^2 matrix image, 512 sampled points at $8\mu\text{s}$ per point would result in a 62.5 kHz bandwidth. This operation is illustrated in Figure 2. This ‘classical’ implementation has a number of drawbacks. First, after the signal is split, the two channels must be exactly matched in both amplitude and phase. This is difficult to accomplish over a wide bandwidth. Second, the demodulation process places dc at the center of the signal bandwidth, with the result that any low-frequency noise causes a center frequency artifact (usually seen as a faint central line in an image). Last, quantization noise in the ADCs limits the overall S/N performance of the system.

Figure 2 Classical receiver representation demonstrating the demodulation of incoming signal θ into in-phase and quadrature components by the use of parallel mixers to remove the rf carrier. After the mixers are low-pass filters (LPF), followed by analog-to-digital converters (ADCs)

Figure 3 Digital receiver representation demonstrating the same operational steps as shown in Figure 2. The initial signal is filtered and mixed to an intermediate frequency which is one-fourth of the ADC sample frequency. A digital down-converter (DDC) performs final demodulation and low-pass filtering

2.2.1 Digital Receiver Implementation

Turning now to a digital receiver (Figure 3), the basic difference in design is that the NMR signal is mixed down to some intermediate frequency and digitized by a single ADC, so that final demodulation, separation into I and Q channels and low-pass filtering is performed in the digital domain.⁴ The ADC is set to a fixed sampling frequency, operating at $N \times \text{IF}$ where IF is the intermediate frequency. Generally, $N = 4$, i.e., fourfold oversampling, is used. The choice of IF is determined by the maximum sampling rate of the ADC, but, in general, should be as high as possible, for two reasons. First, it dictates the minimum sampling interval, which then impacts the total sampling period, which then in turn can place a limitation on minimum echo time (TE). Second, to maximize S/N, the ratio between final subsampled baseband sampling rate and the IF should be as great as possible. This minimizes the ADC quantization noise per unit bandwidth.⁵ There is another trade-off to be made when selecting the intermediate frequency, namely, the word depth of the ADC, i.e., the number of bits. As the number of bits decreases, conversion speed increases. For example, 8-bit converters can operate at speeds up to 100 MHz, whereas 16-bit converters only up to 1 MHz are readily commercially available. Quantization noise magnitude is determined by the voltage step size of the converter, and S/N is therefore proportional to $2^N / \sqrt{\text{(conversion rate)}}$, where N is the number of bits in the converter. In other words, from a quantization noise perspective, a 14-bit converter operating at 4 MHz is equivalent to a 16-bit converter operating at 0.5 MHz.

To achieve the equivalent function of quadrature phase-sensitive detection for fourfold oversampled data, the input data stream is multiplied by the cosine and sine of the IF, which simplifies to multiplication by $+1, 0, -1, 0, \dots$ for one channel and $0, +1, 0, -1, \dots$ for the other. This process generates an exact 90° phase difference between channels, and centers the signals around dc. Low-frequency analog noise that in an analog receiver manifests self as a 'dc' artifact in the scheme just described is placed outside the imaging bandwidth so that the need for dc correction is eliminated. A second stage of digital filtering is implemented in each demodulated channel to provide the variable sampling required by the MR sequences. Finite-impulse-response (FIR) filters⁶ perform this operation. These are multistage, linear phase filters, which are ideally suited to an implementation in silicon because of their repetitive pipelined operation. The selectable output sampling rate

required by the NMR pulse sequence is achieved by choice of the decimation factor, which is the difference between input and output rates from the filters. FIR filter characteristics are more variable than their analog counterparts. Whereas the roll-off of an analog filter is determined by the number of poles (or filter stages), so that, for example, a six-pole filter attenuates at 36 dB per octave, the FIR filter design process allows tailoring of roll-off by trading final attenuation value (stopband attenuation) with rate of attenuation and ripple within the passband. FIR filters are defined in terms of the number of 'taps' they contain, where each tap represents a multiply-accumulate operation. With increasing decimation factor, a larger number of taps are needed to implement a filter with effective attenuation (> 80 dB at twice the corner frequency). Therefore, narrowband filters, such as would be used in spectroscopy sequences, require a greater number of taps, potentially up to 256, whereas for an imaging sequence with a decimation factor of say 32 only about 32 taps may be needed. While cut-off frequencies can be extremely sharp, with filters designed with many taps, actual implementation may require a large number of devices. In early digital receiver systems, each of the functions described above were implemented with individual digital devices. Today, the key building block for a current state of the art digital receiver is known as a digital down-converter (DDC). This is a single chip synthesizer, quadrature mixer, and lowpass filter, whose input is a sampled data stream taken directly from the ADC. Devices are available that can handle data up to 16-bits wide at a 52 MSPS (mega-samples-per-second) rate. The complex result of the demodulation process is lowpass-filtered with identical filters in the in-phase (I) and quadrature (Q) processing chains. Lowpass filtering is accomplished via a high decimation filter (HDF), followed by a fixed finite-impulse-response (FIR) filter. The devices provide automatically optimized matched bandwidth in that the lowpass filter inherently tracks the output (decimated) sampling rate. FIR filter coefficients are generated internally to the chip, so no preprogramming of filter parameters is required. Another advantage of the DDC is that automatic quadrature spectral reversal can be performed. In techniques such as EPI where echoes are taken alternately from read gradients of opposite sign, the frequency of each readout is therefore reversed and must be reordered. This is accomplished in the DDC by translating the lower sideband of the input to baseband rather than the upper sideband.

Figure 4 (a) A plot of image noise versus receiver attenuation for both analog and digital receivers operating at a 16 kHz bandwidth. Note the improved linearity at high attenuation factors (corresponding to high signal strength). (b) Data plotted for the same noise conditions as in (a), except with a 4 kHz bandwidth. The linearity and dynamic range of the digital system are unchanged, whereas the quantization noise per unit bandwidth of the analog system has increased fourfold

2.3 Experimental Validation of Digital Spectrometer S/N Improvements

An experimental validation of the relative performance between analog and digital receivers has been conducted (S. Mitchell, personal communication). The focus was to demonstrate that the reduced quantization noise of the digital receiver was reflected in actual image S/N improvement. An MR imaging system with identical 'front end' configuration (coils and preamplifiers), but different 'back end' equipment (spectrometer, data acquisition, and processing and display

computers) was used. Images using identical scan parameters were taken first with the analog spectrometer and then with the digital spectrometer. Since the gains of the two spectrometers were different, the image pixel values and spectrometer input attenuator values were used to compute the gain difference between the two units. Then, a series of 'air scans' were taken at different receiver gain settings for the two spectrometers, with the standard deviation of the image noise being measured at each gain setting.

The results are shown in Figures 4(a) and (b). With increasing attenuation (i.e., as signal magnitude increases), the

image noise as evidenced by standard deviation measurement exhibits progressively nonlinear behavior. In Figure 4(a), the response for digital and analog receivers is plotted for effective sampling at $16\mu\text{s}$ per point. This shows that the digital receiver exhibits about another 12 dB of dynamic range over its analog counterpart. The situation is demonstrated even more clearly for narrow bandwidth sequences. As shown in Figure 4(b), where data for a sampling rate of $64\mu\text{s}$ per point are plotted, the analog receiver performs even more poorly relative to the digital design. The linearity of response for the digital system is unchanged by switching bandwidth whereas the analog system S/N drops by 6 dB. This is because the quantization noise per unit bandwidth for the digital system is fixed, but the quantization noise generated by the ADCs in the analog implementation is now spread over a fourfold-narrower bandwidth, thus increasing the noise per unit bandwidth. The practical effect of this is to cause the signal magnitude at which reduced image S/N is visualized to be reduced.

2.4 Implementation of Multichannel Systems

Digital rf architecture is readily amenable to configuration in multichannel systems for both transmitter and receiver. In MRI, the most common use is in multichannel receive systems used with phased array rf coils. In such schemes, individual rf receive coil elements are formed into an array to cover the anatomical region of interest.⁷ Each array element is connected to a separate receiver, and the resultant receive signals, either before or after Fourier transformation to the image domain, are combined to form a single image. The digital receiver implementation where the demodulator is connected to a digital signal processor (DSP) is particularly suited to the processing of phased array data. The DSP can be used for preprocessing of data to give weighted summation and correction for amplitude and/or phase variation between channels. The compact nature of a digital receiver design allows multiple receive channels to be configured on a single PC board, thus reducing the cost and complexity of multichannel systems and allowing the S/N advantages of phased array designs to be achieved without significant increase in system equipment. The use of a local NCO for receiver offset frequency allows each receiver in a multichannel array to have a unique demodulation frequency. This can be used to advantage for avoidance of aliasing and in the implementation of arrays where final composite images are not required, such as when used for imaging bilateral structures (e.g., TMJ). In addition, a multichannel system can be used advantageously with conventional quadrature coils by feeding each of the coil quadrature pair outputs to a separate receiver. This can improve performance by allowing for amplitude and phase balance as discussed above, but also can improve S/N by eliminating losses in analog hybrid combiner circuits, since these circuit components are not required.

3 CONCLUSIONS

Digital rf technology has now been widely adopted for use in MR imaging spectrometers, and is the technology of choice

for new designs. Since initially demonstrated in the mid to late 1980s, advances in the speed and degree of integration of the digital devices required to implement spectrometer functions on both the transmitter and receiver side have increased dramatically. Other than the D/A converter (DAC) on the transmit side and the A/D converter (ADC) for the receiver, it is now possible to construct a spectrometer for a low- to mid-field system with only two devices—a single digital device for transmitter and a second for the receiver. With this degree of integration and forecasted improvements in speed of operation, the majority of whole body MR systems are expected to utilize direct-conversion digital spectrometers. In addition, because of the high degree of integration of digital spectrometers, it is anticipated that multichannel systems will become the operating standard in the near future. The inherent programmability and built-in self test features of the digital systems are also beneficial to reducing set-up and calibration time. The digital designs offer improvements in terms of accuracy and precision, and on the receive side can demonstrate improved dynamic range, which can be translated into improved S/N for high signal scans.

Whole Body MRI: Local and Inserted Gradient Coils

Eric C. Wong

Medical College of Wisconsin, Milwaukee, WI, USA

1 INTRODUCTION

The gradient subsystem of the MRI scanner is responsible for all forms of spatial encoding, including image formation, encoding of flow information, encoding of diffusion information, and spatial modulation of magnetization for tissue tagging and selection of desired coherences (see also *Gradient Coil Systems*). In many applications, the quality of the data obtained is limited by hardware-imposed limitations on the gradient amplitude or the gradient slew rate. Two examples are echo planar imaging (EPI),¹ which is typically limited in its spatial resolution by gradient amplitude and slew rate, and diffusion imaging,² which is limited primarily by gradient amplitude to very long echo times on conventional whole body systems.

Local gradient coils (LGCs) are gradient coils that are smaller than the whole body gradient coils built into clinical imaging systems, and are designed for specific purposes or areas of anatomy. Their smaller size gives them two advantages over whole body gradients.

The first advantage is that LGCs can produce stronger gradients per unit current, and higher gradient slew rates per unit voltage than whole body coils. For many clinical imaging systems, the use of local gradient coils makes more imaging techniques feasible (such as EPI), and improves the performance of many other techniques (i.e., higher resolution, shorter *TE*, etc.). This advantage is a technical and practical one. It brings higher performance gradients to clinical systems in a convenient and inexpensive way because local gradient coils are relatively simple add-on components, much like local rf coils, which are very widely used. However, there is active research at several institutions in the development of more powerful electronics to generate the current and voltage necessary to create strong, rapidly switched gradients using whole body gradient coils, and several commercial units are already available.

The second advantage is that LGCs can create higher gradient slew rates for a given limit on field slew rate. Because time-varying magnetic fields can induce electric currents and neuronal stimulation, there are limits on maximal field slew rates allowed in humans. In the United States, the FDA currently sets this limit at 20 T s^{-1} . This field slew rate can be achieved not only using local gradient coils, but also by some of the higher performance whole body gradient systems available today. However, a local gradient coil will in general create a lower field slew rate for a given gradient slew rate, because the physical extent of the fields generated by a local gradient coil is smaller. For example, if a whole body Z gradi-

ent coil is used to image the head, the peak field will be in the area of the mid-chest, while the peak field of a local head gradient coil will be in the neck, and will be two to three times lower for a given gradient. This advantage is a more fundamental one in that local gradient coils can achieve stronger and faster switching gradients than whole body gradient systems, regardless of advances in whole body gradient system technology.

The primary disadvantage of using local gradient coils is that they add some complexity to the subject set-up procedure. The added time and effort are similar to that of using specialized rf coils, and, as local gradient coils become more common, commercialized, and integrated into gradient/rf coil units, the additional set-up time should be minimal. In some cases, patient comfort is decreased by the presence of local gradient coils owing to decreased visibility, restriction of patient movement, or acoustic noise. For a given imaging technique, LGCs are generally quieter in operation than whole body gradients. However, because LGCs allow the use of stronger and more rapidly switched gradients, acoustic noise at higher frequencies can be generated, and can attain high sound pressure levels (SPL). The SPL during EPI scanning in a local head gradient coil is approximately 100 dB, but is easily attenuated to tolerable levels using standard (30 dB) foam earplugs.

2 SAFETY

Two potential safety hazards accompany the use of LGCs: mechanical injury from forces and torques on the coil, and injury from electrical currents and voltages.

LCGs are usually designed so that there is no net force of torque on the coil when the coil is in place for imaging. However, if the coil is moved to an inhomogeneous area of the static field, or a portion of the coil fails without opening the circuit, then net forces and torques can result. If 100 A is applied to a coil in a 1.5 T field, torques on the order of 100 N m can be generated in a head gradient coil. If the coil is in an inhomogeneous portion of the field then forces on the order of 1000 N can result. Therefore, the system should be safeguarded so that current cannot be applied when the coil is not in place for imaging. The coil structure and support system should be strong enough to withstand the internal forces encountered during normal operation, and to prevent injury in case of an internal short.

The maximum voltage that drives most LGCs is on the order of 300 V. Although this is enough to cause injury, voltages of this magnitude are easily insulated from patients with only minimal measures such as plastic insulation. However, care must be taken, especially during installation and removal of the coil, that high voltage does not appear at any accessible terminals.

3 DESIGN CONSIDERATIONS

Many factors must be taken into account in the design of local gradient coils, including coil geometry, size, anatomy of interest, desired gradient strength, efficiency, inductance, desired switching rate, eddy currents, gradient uniformity, forces and torques, heat dissipation, and bioeffects. A large

number of trade-offs exist between these factors, and only basic principles are discussed here.

The geometry of LGCs, like that of local rf coils, can be divided into three categories:

1. whole volume coils, which completely surround the anatomical structure of interest;
2. partial volume coils, which partially surround the structure;
3. surface gradient coils, which are placed against one side of the structure.

The primary deciding factor in the choice of coil geometry is the structure of the anatomical region of interest (ROI). If a whole volume coil can be placed around the ROI, as is usually the case for the head and the upper and lower extremities, this is generally preferable from the point of view of coil efficiency (gradient per unit current) and gradient field uniformity. The main drawbacks of whole volume coils are that they limit access to the patient, and they interfere more strongly with the rf fields. For large structures such as the chest and abdomen, a whole volume coil would be essentially a whole body coil. In order to obtain the advantages of smaller coils in these structures, partial volume or surface coils must be used. These will, in general, have smaller regions of usable gradient field uniformity, but can be useful for imaging of relatively small or superficial anatomical structures such as the heart.

The advantages gained by the use of a LGC have a strong dependence on the size of the coil. Two of the desirable properties of gradient coils are high efficiency and low inductance. For a coil of a given design, with a fixed number of turns,

$$\text{Efficiency} \propto \frac{1}{\text{size}^2} \quad (1)$$

$$\text{Inductance} \propto \text{size} \quad (2)$$

These factors indicate that the size of the coil should be as small as possible. The lower limit on the size of the coil is set by three other factors:

1. the coil must have a region of usable gradient field uniformity (the coil ROI) that encompasses the anatomical ROI;
 2. the coil itself must be large enough to accommodate the anatomy of interest;
 3. sufficient room must be left for the rf structure and return flux to allow dominant loading of the rf coil by the subject.
- The largest of these three lower limits should, in general, determine the optimum size of the coil.

Once the desired gradient strength has been determined, the gradient coil should be designed to generate the required gradient and not more. If the available gradient strength is unnecessarily large then the inductance is higher and the maximum switching rate slower than they could otherwise have been. An exception to this principle can occur for the case of small coils in which the number of turns of wire required to produce the desired gradient is small, and may not be sufficient to produce the desired gradient field uniformity.

The inductance of a coil limits its maximum switching rate. A gradient coil can be thought of as a series resistance/inductance circuit. For a step voltage V_0 applied to the terminals of this circuit, the current will have the form

$$I = \frac{V_0}{R} (1 - e^{-Rt/L}) \quad (3)$$

where L and R are the inductance and resistance of the circuit, respectively. Thus the current decays towards the final current with a time constant L/R . From this, it appears that either decreasing the inductance or increasing the resistance will decrease the switching time, but this is usually not the case. In practice, if an abrupt change in the current is desired, the voltage is not simply stepped to its new equilibrium value, but is given a 'pre-emphasis' pulse, which is a large overshoot of the voltage in order to increase the current slew rate. As the desired current is approached, the voltage is decreased to its equilibrium value. The current slew rate is limited by the maximum voltage output of the gradient amplifier ($V_{\max}$), which is usually much higher than the voltage required to sustain the maximum current at steady state. The maximum current slew rate is calculated by differentiating the above equation with respect to time, replacing V_0 with $V_{\max}$:

$$\left(\frac{\partial I}{\partial t}\right)_{\max} = \frac{V_{\max}}{L} e^{-Rt/L} \quad (4)$$

For ramps that are short compared with L/R , as is usually the case, the current slew rate is simply $V_{\max}/L$. Therefore, if fast switching is important to an application, the inductance of the gradient coil used should be minimized.

The importance of fast switching rates varies greatly, depending upon the imaging technique. For diffusion imaging using pulsed field gradients in a conventional spin echo sequence, the diffusion weighting gradient must have a large amplitude to minimize TE , but the switching rate of the gradient is, in general, not critical. For such an application, a gradient coil with many turns, a high efficiency, and a relatively high inductance would be practical. For fast imaging techniques such as echo planar, fast gradient switching speed is critical to the performance of the technique, and a coil with a minimum acceptable efficiency and low inductance should be used.

Eddy currents are currents induced in conducting structures due to time-varying magnetic fields. Eddy currents generate fields that oppose the field variations that induced the currents. Gradient eddy currents effectively limit the field slew rate by creating transient fields that usually oppose the desired gradient fields. Structures in an MRI scanner that may support eddy currents include the cryostat, the rf coil, and the rf shield. For whole body gradient coils, eddy currents generated in the cryostat are usually of the greatest concern, because the cryostat is physically close to the gradient coil and has very low resistance. In general, LGCs are much smaller than whole body gradient coils, and couple much less strongly to the cryostat. However, if rf coils or shields that have low-resistance closed current paths are used in close proximity to the gradient coil then these can support eddy currents and degrade the gradient field waveforms. Close attention to this problem must be paid in the design of rf coils and shields for use with local gradient coils.

Because the gradient fields directly map the spatial coordinates of physical space to the coordinates of the image, perfect gradient field uniformity is desired. However, if the gradient fields are not perfectly linear but are known then spatial transformations can be applied to the images to determine the

location in space from which the signal in each pixel came. This can partially alleviate the problems associated with using nonlinear gradients, but several problems remain. In 2D imaging—the most common type—if the slice select gradient is nonuniform then information is obtained from tissue outside of the desired slice and the slice cannot be correctly reconstructed. If 3D data are collected, or if the slices are contiguous, then 3D spatial transformations can be used. Spatial transformations to correct for nonlinear gradients are straightforward, but increase image reconstruction time. Because nonlinearities in the gradients cause variations in the voxel sizes, the signal intensity, signal-to-noise ratio (S/N), and spatial resolution will be modulated by these variations, potentially adding to the difficulty of image interpretation. An interesting possibility is also raised by the availability of nonuniform voxel sizes. If gradient and rf coils with matched field nonuniformity are used then images with uniform S/N could be obtained using rf coils with high sensitivity but very nonuniform sensitivity profiles, such as surface rf coils.

If gradient pulses are used for functions other than spatial encoding then these functions will be affected by gradient nonlinearities as well. Nonlinear diffusion weighting or flow-encoding gradients will cause spatial variations in the diffusion or flow weighting. Gradient pulses that are used to dephase transverse magnetization will have an effectiveness that has spatial variations if the gradients are nonlinear.

The currents carried by a gradient coil interact with both the static field and self-generated fields. Because the static field is much stronger than the gradient fields for high- and mid-field scanners, interaction with the static field is of greater concern, and large forces on the current-carrying elements can result. In a uniform static field, a closed current loop cannot experience net forces, but can experience net torques. If these torques are not internally balanced then the coil must be mounted in a very strong and rigid mechanical structure that is tied to the structure of the main magnet in order to prevent large-amplitude vibration of the coil. Torques on an unbalanced head coil in a 1.5 T field are on the order of 100 N m. Internal balancing of the torque in a coil can be achieved by symmetry or by explicit nulling of the torque moment in an asymmetrical design.

4 DESIGN TECHNIQUES

Numerous mathematical techniques have been used to design gradient coils, many of which are described in a review article by Turner.³ Most designs to date describe current patterns on the surface of one or two cylinders, since this is the most natural geometry for whole body patient access, and for LGCs a natural geometry for the head and extremities. Early designs consisted of simple counter-rotating pairs of loops for longitudinal gradients, and saddle coils for transverse gradients. Romeo and Hoult⁴ used a spherical harmonic expansion of the fields to produce simple coils that approximate the lower order harmonics. These were then combined to approximate the desired fields. These designs give linear gradient fields in only a relatively small fraction of their enclosed volume, but are simple, easy to construct designs that can be useful if gradient uniformity is not critical.

Compton⁵ introduced direct inversion of the field equations to derive a distribution of current density that would produce a desired field pattern. He defined an error function to describe the uniformity of the gradient fields over a region of interest, and used a least-squares approach to minimize this function. This approach can directly derive a current distribution that creates the desired fields for any coil geometry and any shape region of interest. The derived current density is approximated by a set of wires or etched current paths to arrive at a final coil design.

Turner⁶ introduced an elegant approach to explicitly minimize inductance while creating the desired fields within the region of interest. Inductance is a quantity that is difficult to minimize using other techniques, because every element of the coil contributes not only self-inductance, but also mutual inductance with all other elements of the coil. For a given coil geometry, an appropriate transform applied to the current density linearizes the inductance so that each element of the design has zero mutual inductance with all other elements. For planar and cylindrical geometries, simple 2D Fourier transformation serves this purpose. In the transformed space, the inductance is a linear function of the transform components, and a Lagrange multiplier technique can be used to satisfy the desired field constraints while minimizing inductance. After deriving a current density pattern in transform space, a reverse transform is applied to produce a current density pattern in physical space, and again approximation by discrete current paths gives a final design. Several variations of the minimum inductance technique have been introduced to apply the technique to different geometries, and to use the same principles to minimize power dissipation instead of inductance.

Another class of design techniques uses numerical methods to optimize combinations of gradient uniformity, inductance, and coil efficiency. Using either a parameterized or a point-by-point description of the current path, mathematical techniques such as gradient descent, simulated annealing, Monte Carlo, and simplex can be used to minimize the chosen cost function. The author has used gradient descent techniques to design some of the coils that are shown in the examples below.⁷ Numerical methods are, in general, more computationally intensive than analytical techniques, but they allow incorporation of arbitrary physical constraints in a simple manner, and they directly produce final designs, avoiding errors that may be introduced by the approximation of continuous current densities by discrete wires.

5 EXAMPLE COIL DESIGNS

Examples of whole volume, partial volume, and surface gradient coils are shown here.

The head coil shown in Figure 1 is an example of a whole volume local gradient coil. It is a three-axis design, torque-balanced by symmetry, and designed using gradient descent for gradient linearity. It was designed for EPI of the human brain, taking into account the specifications of the system in which it was to be used. The scanner it was designed for has a maximum sampling rate of 125 kHz and gradient amplifiers with a nominal current output of 85 A. The coil was designed to produce 20 mT m^{-1} gradients at 85 A, giving a minimum field of view of 16 cm at 125 kHz bandwidth, which was the smallest

Figure 1 Three-axis local head gradient coil

Figure 3 Three-axis surface cardiac gradient coil

anticipated useful field-of-view in the human brain. Because the minimum coil efficiency for the application was specified, the number of turns of wire was kept to a minimum, and very low inductance was achieved. Inductances of 0.08–0.17 mH for the three axes allow switching times below 100 μ s.

Figure 2 shows a biplanar cardiac gradient coil—an example of a partial volume coil. Although the coil structure encloses the chest for mechanical stability, the current-carrying elements occupy only two 30 cm $\times$ 40 cm rectangular regions, one above and one below the patient, making it in principle a partial volume coil. This coil produces only a single axis gradient in the vertical direction, and therefore requires the use of the whole body axial and horizontal gradient for imaging. It was also designed by gradient descent, and is used for EPI of the human heart. Because it only generates a vertical gradient field, only axial and sagittal EPI imaging, as well as oblique imaging intermediate to these, is possible.

Figure 3 shows a surface cardiac gradient coil. This coil is a three-axis design, upon which the patient lies prone, and generates nonlinear gradient fields that fall off by a factor of approximately two from the anterior surface to the posterior surface of the heart. The surface coil design in this case was chosen primarily for patient comfort, since the chest is not enclosed in the coil structure. This coil is used in conjunction

with a surface rf coil, giving nearly uniform S/N across non-uniform voxel sizes, as described above.

6 APPLICATIONS

The most straightforward applications of LGCs are in high-resolution and short- TE conventional imaging techniques, which are usually severely limited by available gradient strength in whole body systems. In principle, high resolution can be obtained using lower gradient strengths and longer pulse durations, but, in practice, the resolution will be limited by the T_2^* of the tissue. It is therefore often necessary to obtain high-resolution images with short TE and data acquisition times. An example is the image of the proximal interphalangeal joint of the human finger shown in Figure 4.⁸ This image was acquired using a cylindrical LGC of 10 cm diameter and a small

Figure 2 Single axis biplanar cardiac gradient coil

Figure 4 Axial image through the proximal interphalangeal joint of the middle finger. Acquisition parameters: gradient echo, FOV 3 cm $\times$ 1 mm, TE = 12 ms, matrix 256 $\times$ 256, TR = 500 ms, flip angle 90°, two excitations

Figure 5 Single shot axial EPI image of the head. Acquisition parameters: single shot spin echo EPI, matrix 128×128 partial k -space, $TE = 20$ ms

transmit–receive rf coil. The gradient strengths used were 60 mT m^{-1} in the slice select direction, and 27 mT m^{-1} in the in-plane direction.

An example of ultrafast imaging using a LGC is shown in Figure 5. This is a single shot EPI image of the human head acquired in 80 ms (see *Echo-Planar Imaging*). For this image, the head gradient coil of Figure 1 was used, and no correction for gradient nonuniformity was employed. Only 15 mT m^{-1} gradients were used, but the coil was switched in just $112 \mu\text{s}$ using standard gradient amplifiers.

An extension of the EPI technique is functional neuro-imaging using either BOLD contrast or flow-dependent contrast.^{9–11} An example using BOLD contrast is shown in Figure 6. In this example, gradient-recalled EPI images through the motor cortex were collected repetitively while the subject alternately performed right and left finger tapping tasks. The figure shows a difference image between images acquired during right finger tapping and images acquired during left finger tapping, clearly demonstrating synchronous modulation of signal from the motor cortices with opposite phase.

Diffusion imaging is an example of the use of strong gradients for encoding of desired contrast, rather than for image formation (see *Methods and Applications of Diffusion MRI*). Figure 7 shows a calculated diffusion image of the eye of an anesthetized rabbit. This image was collected using the same 10 cm diameter LGC as that used to acquire Figure 4, inserted into the same clinical scanner. Diffusion weighting was achieved using pulsed gradients of 80 mT m^{-1} and 12 ms duration, resulting in a b factor of approximately 400 s mm^{-2} . With these gradients, the minimum TE for a conventional spin echo imaging sequence was 30 ms, similar to the average T_2 of the lens, which was the object of interest. If similar diffusion weighting is to be achieved using typical whole body gradients (10 mT m^{-1}), the minimum TE would be approximately 200 ms, which is many times longer than the T_2 of the tissue, and very little signal would be collected.

There are many other applications of LGCs for which examples are not shown. In angiography, stronger and faster gradients allow for shorter flow-compensating gradients and hence shorter TE . This decreases flow-related dephasing and increases the detected signal. In magnetic tissue tagging, such

Figure 6 Calculated axial image of functional activation in the motor cortices during alternating right and left finger tapping. Acquisition parameters: single shot gradient-recalled EPI, 100 repetitions at 1 s intervals with five alternating periods of right and left finger tapping, matrix 64×64 , $TE = 40$ ms. The displayed image is a subtraction of images collected during left finger tapping minus images collected during right finger tapping

as myocardial tagging to observe cardiac wall motion, stronger gradients can improve tag profiles and decrease tagging time, thus generating sharper tagged grids in the final images. For imaging of very short T_2^* species, it is necessary to employ

Figure 7 Calculated diffusion coefficient image of the normal rabbit lens. Acquisition parameters: spin echo with pulsed field gradients on either side of the refocusing pulse, b factor 400 s mm^{-2} , direction of diffusion sensitivity left/right on image, FOV $3 \text{ cm} \times 1 \text{ mm}$, $TE = 30$ ms, matrix 256×256 , $TR = 500$ ms, two excitations

strong gradients in order to assure that the imaging gradients dominate the static field inhomogeneities. Short T_2^* occurs primarily in areas with strong susceptibility gradients, such as lung tissue. In localized spectroscopy, spectral resolution can be severely compromised by the presence of gradient eddy currents. For this reason, gradient switching rates are in general very conservative, resulting in relatively long minimum echo times. For shorter- T_2 species, LGCs can be used to improve switching rates with minimal eddy currents, and thereby decrease echo times.

7 SUMMARY

Many applications in MRI are either dependent upon or improved by the availability of stronger and more rapidly switched gradients than are typically found in whole body clinical systems. The use of local gradient coils is a simple and inexpensive means of obtaining high-performance gradients, and has the advantage of higher permissible gradient switching rate than whole body coils for a given limit on field switching rate.

Image Processing of Functional MRI Data

Karl J. Friston

The Wellcome Department of Cognitive Neurology, London, UK

1 INTRODUCTION

This chapter reviews the issues that arise when using functional MRI (fMRI) to make inferences about functional brain architectures. These include issues common to all functional neuroimaging and some considerations that are special to fMRI. The general issues pertain to the relationship between neurobiological hypotheses and models of what one expects to see and how they are realized in terms of the statistical models used to analyze fMRI time series. Because fMRI encompasses areas of interest to many specialities, this chapter initially defines some technical terms that are commonly encountered. It continues with a review of the distinction between functional specialization and integration and how these principles serve as the motivation for most analyses of fMRI data.

1.1 Glossary of Terms

AR(n) Autoregression model of order n for a time series that obtains by taking a linear compound of the previous n values and an independent component (usually referred to as an innovation). For every AR(n) model, there is an equivalent representation in terms of a moving average of the innovation.

Contrast A linear compound (i.e., weighted linear combination) of the parameter estimates from a general linear model. The compound is specified by series of contrast weights.

CVA (*Canonical variates analysis*) The identification of patterns of activity in terms of the generalized eigen-vectors of the covariance matrices of the fitted effects and residuals of a multivariate time series.

EC (*Euler characteristic*) A topological measure that is applied to some excursion set of a Gaussian field. The excursion set comprises all components that exceed a threshold (the EC is roughly equivalent to the number of blobs minus the number of holes).

Efficiency The inverse of the variance of the estimated parameters of a model.

Effective connectivity The influence that one neuronal system exerts over another in terms of measurable changes in activity.

Functional connectivity The temporal correlations between measurable changes in activity in two brain areas.

FIR (*finite impulse response*) Response of a system to an impulse expressed over a finite series of discrete times.

Gaussian field theory The mathematical framework describing spatially extended multidimensional stationary stochastic fields. SPMs (qv) are assumed to be good lattice approximations to realizations of Gaussian fields.

General linear model The mathematical basis of most parametric statistics; it expresses a response variable in terms of a linear combination of explanatory variables and a multinormal error term with known correlations.

HRF (*hemodynamic response function*) Regionally specific FIR (qv) to some underlying neuronal impulse, expressed in terms of fMRI signal changes.

ICA (*independent component analysis*) The identification of patterns of activity that render the associated time-variables independent.

LTI (*linear time-invariant*) Used to describe systems with stationary and linear input–output characteristics.

PCA (*principal component analysis*) The identification of patterns of activity in terms of the eigen-vectors of the covariance matrix of a multivariate time series.

Resel (*resolution element*) The volume of an elementary image component defined by its intrinsic smoothness.

Sensitivity The probability of getting a true positive (i.e., β where β is the probability that some statistic reaches criterion given the alternative hypothesis is true).

Specificity The probability of getting a true negative (i.e., $1-\alpha$ where α is the probability that some statistic reaches criterion given the null hypothesis is true). Specificity is sometimes expressed directly in terms of α (the probability of a false positive).

SOA (*stimulus onset asynchrony*) The time intervals between successive onsets of stimuli.

SPM (*statistical parametric map*) An image process of statistical values with a known multivariate distribution under the null hypothesis (usually images of Student's T or F statistic).

SVD (*singular value decomposition*) Orthogonal decomposition of a matrix commonly employed in PCA (qv).

Volterra series A functional Taylor expansion of a functional of a [vector] function of time. This expansion is commonly construed as a polynomial expansion with 'memory' or a nonlinear convolution of the [vector] function (input) to give the functional (output) of a nonlinear system.

1.2 Overview

Statistical parametric mapping (SPM) is generally used to identify functionally specialized brain regions and is the most prevalent approach to characterizing functional anatomy. The alternative perspective, namely that provided by functional integration, requires a different set of (multivariate) approaches that examine the relationship between changes in activity in one area and another. SPM is a voxel-based approach, employing standard inferential statistics to make some comment about regionally specific responses to experimental factors. In order to assign an observed response to a particular brain structure or cortical area, the data must conform to a known anatomical space. Before considering statistical modeling, this chapter deals with how a time series of images are realigned and mapped into some standard anatomical space (e.g., stereotactic space). The general ideas behind SPM are then described and illustrated with attention to the different sorts of inference that can be made with different experimental designs. fMRI is special in the sense that the data lend themselves to a signal processing perspective that can be exploited to ensure that both the design and analysis are as efficient as possible. Linear time

invariant (LTI) models provide the bridge between inferential models employed by statistical mapping and simple signal processing approaches. Temporal autocorrelation in noise processes represents another important issue, specific to fMRI, and approaches to maximizing efficiency in the context of serially correlated error terms will be discussed. Nonlinear models (Volterra series) will be considered because they provide constraints on when the assumptions behind linear models are likely to hold. fMRI can capture data very fast (in relation to other imaging techniques) allowing event-related responses to be measured. The distinction between event- and epoch-related designs will be discussed from the point of view of efficiency and the constraints provided by nonlinear characterizations. Before considering multivariate analysis and effective connectivity in the final section we will close the discussion of inferences about regionally specific effects by looking at the distinction between fixed and random effect analyses and how this relates to inferences about the subject studied or the population from which these subjects came.

2 FUNCTIONAL SPECIALIZATION AND INTEGRATION

The brain appears to have two fundamental principles of functional organization, *functional integration* and *functional specialization*, where the integration within and among specialized areas is mediated by effective connectivity. The distinction between these principles relates to that between localizationism and disconnectionism, which dominated thinking about cortical function in the nineteenth century. Since the early anatomic theories of Gall, the identification of a particular brain region with a specific function has become a central theme in neuroscience. However, functional localization per se was not easy to demonstrate. For example, a meeting that took place on 4 August 1881 addressed the difficulties of attributing function to a cortical area given the dependence of cerebral activity on underlying connections.¹ This meeting was entitled ‘Localisation of function in the cortex cerebri’. Goltz accepted the results of electrical stimulation in dog and monkey cortex but considered this excitation method was inconclusive in that movements elicited might have originated in related pathways, or current could have spread to distant centers.² In short, the excitation method could not be used to infer functional localization because localizationism discounted interactions, or functional integration, among different brain areas. It was proposed that lesion studies could supplement excitation experiments; ironically, it was observations on patients with brain lesions³ some years later that led to the concept of disconnection syndromes and the refutation of localizationism as a complete or sufficient explanation of cortical organization. Functional localization implies that a function can be localized in a cortical area, whereas specialization suggests that a cortical area is specialized for some aspects of perceptual or motor processing, and that this specialization is anatomically segregated within the cortex. The cortical infrastructure supporting a single function may then involve many specialized areas linked by functional integration. In this view, functional specialization is only meaningful in the context of functional integration and vice versa.

2.1 Functional Specialization and Segregation

The functional role played by any component (e.g., cortical area, subarea, or neuronal population) of the brain is largely defined by its connections. Certain patterns of cortical projections are so common that they could amount to rules of cortical connectivity: ‘These rules revolve around one, apparently, overriding strategy that the cerebral cortex uses—that of functional segregation.’⁴ Functional segregation demands that cells with common functions are grouped together. This architectural constraint in turn necessitates both convergence and divergence of cortical connections. Extrinsic connections between cortical regions are not continuous but occur in patches or clusters. This patchiness has, in some instances, a clear relationship to functional segregation. For example, cortical region V2 has a distinctive cytochrome oxidase architecture, consisting of thick stripes, thin stripes, and inter-stripes. When recordings are made in V2, directionally selective (but not wavelength- or color-selective) cells are found exclusively in the thick stripes. Retrograde (i.e., backwards) labeling of cells in region V5 is limited to these thick stripes. All the available physiological evidence suggests that V5 is a functionally homogeneous area that is specialized for visual motion. Evidence of this nature supports the notion that patchy connectivity is the anatomical infrastructure that mediates functional segregation and specialization. If it is the case that neurons in a given cortical area share a common responsiveness (by virtue of their extrinsic connectivity) to some sensorimotor or cognitive attribute, then this functional segregation is also an anatomical one. Challenging a subject with the appropriate sensorimotor attribute or cognitive process should lead to activity changes in, and only in, the area of interest. This is the model upon which the search for regionally specific effects is based.

The analysis of fMRI data involves many steps that can be broadly divided into spatial preprocessing, estimation of the parameters of a statistical model, and making inferences about modeled effects using the parameter estimates and their associated statistics (Figure 1). We will deal first with spatial transformations: the relationship between regionally specific effects and homologous responses in other subjects or non-human primates has to be established in order to understand functional anatomy. This necessitates some form of anatomical designation for regional responses that is facilitated by analyzing the data in relation to some standard anatomical space.

3 SPATIAL REALIGNMENT AND ANATOMICAL NORMALIZATION

The analysis of fMRI studies starts with a series of spatial transformations to reduce artifactual variance components in the voxel time series. The first step is to realign the data in order to ‘undo’ the effects of subject movement during the scanning session. After realignment, the data are then transformed using linear or nonlinear mappings into a standard anatomical space. The data are usually spatially smoothed before being entered into the analysis proper.

3.1 Realignment

Changes in signal intensity from any one voxel can arise from head motion and this represents one of the most serious

Figure 1 Schematic depicting the transformations that start with the fMRI time series and end with a statistical parametric map (SPM). SPMs can be thought of as ‘X-rays’ of the significance of an effect. Voxel-based analyses require the data to be in the same anatomical space: This is effected by realigning the data (and removing movement-related signal components that persist after realignment). After realignment the images are subject to non-linear warping so that they match a template that already conforms to a standard anatomical space. After smoothing, the general linear model is employed to estimate the parameters of the model and to derive the appropriate univariate test statistic at each and every voxel (see Figure 2). The test statistics that ensue (usually T or F statistics) constitute the SPM. The final stage is to make statistical inferences on the basis of the SPM (see Figure 3) and characterize the responses observed using the fitted responses or parameter estimates

confounds in fMRI studies. Despite restraints on head movement, even cooperative subjects still show displacements of up to a millimeter or so. Realignment involves estimating the six parameters of an affine ‘rigid-body’ transformation that minimizes the (sum of squared) differences between each successive scan and the first and applying the transformation by resampling the data using trilinear or sinc interpolation. Estimation of the affine transformation is usually effected with a first-order approximation of the Taylor expansion of the effect of movement on signal intensity using the spatial derivatives of the images. This allows for a simple iterative least squares solution (that corresponds to a Gauss–Newton search).⁵ However, even after perfect realignment, movement-related signals can still persist. This calls for a final step in which the data are adjusted for residual movement-related effects.

3.2 Adjusting for Movement-related Effects

In extreme cases, as much as 90% of the variance in an fMRI time series can be accounted for by the effects of movement *after* realignment.⁶ These movement-related components are the result of subject movement between slice acquisitions, interpolation artifacts, nonlinear distortion through magnetic field inhomogeneity, and spin-excitation history effects.⁶ The last can be pronounced if the repetition time (TR) approaches T_1 , making the current signal a function of movement history.

These multiple effects render the movement-related signal (y) a nonlinear function of displacement (x) in the n th and previous scans $y=f(x_n, x_{n-1}, \dots)$. By assuming a sensible form for this function, its parameters can be estimated using the observed time series and the estimated movement parameters x from the realignment procedure. The estimated movement-related signal is then simply subtracted from the original data. The form for $f(x)$ proposed in Friston et al. was an autoregression 1 [AR(1)] model that was motivated by spin-excitation history effects.⁶ Generally, for TR values of several seconds, interpolation artifacts supersede and an expansion of $f(x_n)$ in terms of periodic basis functions of the current displacement appears to be sufficient.

Movement-related effects require a spatial realignment. In addition, temporal realignment may be required in multislice acquisition to ensure that the data from any given volume were sampled at the same time. This is usually performed using sinc interpolation over time and only when the temporal dynamics of evoked responses are important.

3.3 Spatial Normalization

After realigning the data, a mean image of the time series or some other co-registered (e.g., a T_1 -weighted) image is used to estimate the warping parameters that map it onto some template that already conforms to a standard anatomical space.⁷

This estimation can use a variety of models for the mapping, including: a 12-parameter affine transformation where the parameters constitute a spatial transformation matrix, low-frequency-basis spatial functions (usually a discrete cosine set or polynomials) where the parameters are the coefficients of the basis functions employed, and a vector field specifying the mapping for each control point (e.g., voxel center). In the last the parameters are vast in number and constitute a tensor that is bigger than the image itself. Estimation of the parameters of all these models can be accommodated in a simple Bayesian framework to find the deformation β that has the maximum posterior probability $p(\beta|Y)$ given the data Y , where $p(\beta|Y) \propto p(Y|\beta)p(\beta)$. This reduces to minimizing the likelihood and prior potentials $H(Y|\beta)$ and $H(\beta)$, respectively, where $p(Y|\beta) = \exp\{-H(Y|\beta)\}$ and $p(\beta) = \exp\{-H(\beta)\}$. The likelihood potential is generally taken to be the sum of squared differences between the template and deformed image and reflects the probability of actually getting that image if the transformation is correct. The prior potential can be used in the context of weighted least squares to incorporate prior information about the likelihood of a given transformation. Prior potentials can be determined empirically⁸ or motivated by constraints on the mapping⁹ and play a more essential role as the number of parameters specifying the mapping increases.

In practice, an affine or spatial basis function model is usually used with iterative least squares to minimize the likelihood potential. As with realignment, this involves linearizing with Taylor expansions. A nice extension of this approach is that the difference between the template and index image can be minimized by using a (linear) combination of templates (e.g., depicting gray matter, white matter, cerebrospinal fluid, and skull tissue partitions). This models intensity differences that are unrelated to registration differences and allows different modalities to be co-registered.⁵

3.4 Co-registration of Functional and Anatomical Data

It is useful to be able to co-register functional and anatomical images. However, with echo planar imaging, geometric distortions of T_2^* images, relative to anatomical T_1 -weighted data, are a particularly serious problem because of the very low frequency per point in the phase-encoding direction. Typically, for echo planar fMRI, magnetic field inhomogeneity sufficient to cause dephasing of 2π through the slice corresponds to a 1 voxel distortion in the plane. ‘Unwarping’ schemes have been proposed to correct for the distortion effects.¹⁰ Note that this is not an issue if the functional data are normalized spatially.

3.5 Spatial Smoothing

The motivations for smoothing the data are fourfold: (i) By the matched filter theorem, the optimum smoothing kernel corresponds to the size of the effect anticipated. The spatial scale of hemodynamic responses is, according to high-resolution optical imaging experiments, about 2–5 mm. Despite the potentially high resolution afforded by fMRI, an equivalent smoothing is suggested for most applications. (ii) By the central limit theorem, smoothing the data will render them more parametric in their distribution and ensure the validity of inferences based on parametric tests. (iii) When making inferences about regional effects using Gaussian field theory (see below),

one of the assumptions is that the data are a reasonable lattice representation of an underlying and smooth Gaussian field. This necessitates smoothness to be substantially greater than voxel size. If the voxels are large then they can be reduced by sub-sampling the data and then smoothing (with the original point spread function) with little loss of intrinsic resolution. (iv) In the context of intersubject averaging, it is often necessary to smooth more (e.g., 6 mm) to project the data onto a spatial scale where homologies in functional anatomy are expressed among subjects.

4 STATISTICAL PARAMETRIC MAPPING AND FUNCTIONAL SPECIALIZATION

Functional mapping studies are usually analyzed with some form of SPM where spatially extended statistical processes are constructed to test hypotheses about regionally specific effects.¹¹ SPMs are image processes with voxel values that are, under the null hypothesis, distributed according to a known probability density function (usually Student’s T or F distributions). The success of SPM largely stems from the simplicity of the idea. Namely, each and every voxel is analyzed using any standard (univariate) statistical test. The resulting statistical parameters are assembled into an image: the SPM. SPMs are interpreted as spatially extended statistical processes by referring to the probabilistic behavior of stationary Gaussian fields.^{12–15} Stationary fields model both the univariate probabilistic characteristics of an SPM and any stationary spatial covariance structure (stationary means not a function of position). ‘Unlikely’ excursions of the SPM are interpreted as regionally specific effects, attributable to the sensorimotor or cognitive process that has been manipulated experimentally.

4.1 Different Approaches?

Statistical analysis corresponds to modeling the data in order to partition observed neurophysiological responses into components of interest, confounds, and error. A brief review of the literature may give the impression that there are numerous ways to analyze fMRI time series with a diversity of statistical and conceptual approaches. This is not the case. With only a few exceptions, every analysis presented is a variant of the general linear model. This includes: (i) simple T tests on scans assigned to one condition or another, (ii) correlation coefficients between observed responses and box-car stimulus functions, (iii) inferences made using multiple linear regression, (iv) evoked responses estimated using LTI models, and (v) selective averaging to estimate event-related responses. Mathematically they are all identical. The use of the correlation coefficient¹⁶ deserves special mention because of its popularity in fMRI. The significance of a correlation is identical to the significance of the equivalent T value testing for a regression of the data on some stimulus waveform. The correlation coefficient approach is useful but the inference is effectively based on a limiting case of multiple linear regression that obtains when there is only one regressor. In fMRI, many regressors usually enter into a statistical model. For this reason, the T statistic provides a much more flexible and general way of assessing the significance of regional effects and is preferred over the correlation coefficient.

Figure 2 The general linear model. The general linear model is an equation expressing the response variable Y in terms of a linear combination of explanatory variables in a design matrix X and an error term with assumed or known autocorrelation Σ . In fMRI, the data can be filtered with a convolution matrix S , leading to an augmented general linear model that includes (intrinsic) serial correlations and applied (extrinsic) filtering. Different choices of S correspond to different (de)convolution schema, as indicated on the upper left. The parameter estimates obtain in a least squares sense using the pseudoinverse (denoted by $+$) of the filtered design matrix. Generally an effect of interest is specified by a vector of contrast weights c that give a weighted sum or compound of parameter estimates $c\hat{\beta}$, referred to as a contrast. The T statistic is simply this contrast divided by the estimated standard error (i.e., square root of the estimated variance). The ensuing T statistic is distributed with ν degrees of freedom. The equations for the estimated variance of the contrast and the degrees of freedom associated with the error variance are provided in the right-hand panel. Efficiency is simply the inverse of the variance of the contrast estimate. Discrepancies between the actual and assumed intrinsic correlations (Σ and Σ_a , respectively) can result in systematic bias in the actual and estimated variance of the contrast. These expressions are useful when assessing the relative efficiency and robustness of a model. The parameter estimates can either be examined directly or used to compute the fitted responses (see lower left panel). Adjusted data refers to data from which estimated confounds have been removed. The residuals r obtain from applying the residual forming matrix R to the data. These residual fields are used to estimate the smoothness of the component fields of the SPM used in Gaussian field theory (see Figure 3).

Some researchers construct statistical maps based on non-parametric tests that eschew distributional assumptions about the data.¹⁷ These approaches may, in some instances, be useful but are generally less powerful (i.e., sensitive) than parametric approaches. This approach was based on the (specious) assumption that the residuals in fMRI data are not normally distributed.

4.2 The General Linear Model

The general linear model is an equation $Y=X\beta+\epsilon$ that expresses the observed response variable Y in terms of a linear combination of explanatory variables X plus a well-behaved error term (see Figure 2). The general linear model is variously

known as ‘analysis of covariance’ or ‘multiple regression analysis’ and subsumes simpler variants, like the ‘T test’ for a difference in means, to more elaborate linear convolution models such as finite impulse response (FIR) models. The matrix X that contains the explanatory variables (e.g., designed effects or confounds) is called the ‘design matrix’. Each column of the design matrix corresponds to some effect one has built into the experiment or that may confound the results. These are variously referred to as explanatory variables, covariates, regressors, or, in fMRI, stimulus functions. The example in Figure 1 relates to an fMRI study of visual stimulation under four conditions. The effects on the response variable are modeled in terms of functions of the presence of these conditions (i.e., box-cars smoothed with a hemodynamic response func-

tion) and constitute the first four columns of the design matrix. There then follows a series of terms that are designed to remove or model low-frequency variations in signal caused by artifacts such as aliased biorhythms. The final column is whole brain activity. The relative contribution of each of these columns is assessed using standard least squares and inferences about these contributions are made using T or F statistics, depending upon whether a particular linear combination of these contributions is examined or all of them together. The operational equations are shown in Figure 2. In this scheme the general linear model has been extended¹⁸ to incorporate intrinsic autocorrelations or serial correlation among the error terms and to allow for some specified filtering or smoothing of the data.

These equations can be used to implement a vast range of statistical analyses. The issue is, therefore, not so much the mathematics but the formulation of a design matrix X appropriate to the study design and inferences that are sought. The design matrix can contain both covariates and indicator variables. Each column of X has an associated unknown parameter. Some of these parameters will be of interest (e.g., the effect of particular sensorimotor or cognitive condition or the regression coefficient of hemodynamic responses on reaction time). The remaining parameters will be of no interest and pertain to confounding effects (e.g., the effect of being a particular subject or the regression slope of voxel activity on global activity). Inferences about the parameter estimates are made using their estimated variance. This allows one to test the null hypothesis that all the estimates are zero using the F statistic to give an SPM{F} or that some particular linear combination (e.g., a subtraction) of the estimates is zero using a SPM{T}. The T statistic obtains by dividing a contrast or compound (specified by contrast weights) of the ensuing parameter estimates by the standard error of that compound. The latter is estimated using the variance of the residuals about the least squares fit. An example of contrast weights would be $[-1 \ 1 \ 0 \ 0 \ \dots]$ to compare the differential responses evoked by two conditions, as modeled by the first two condition-specific regressors in the design matrix. If several parameter estimates are potentially interesting (e.g., using polynomial expansions¹⁹ or basis functions of some parameter of interest), then the SPM{F} is usually employed.

An important example, from the perspective of fMRI, of the general linear model is the LTI model.

4.2.1 *The General Linear Model, Linear Time Invariant Systems, and Finite Impulse Response Models*

In Friston et al. the form of the hemodynamic impulse response function (HRF) was estimated using a least squares deconvolution and a FIR LTI model, where evoked neuronal responses are convolved with the HRF to give the measured hemodynamic response²⁰ (see also Boynton et al.²¹). The estimated HRF resembled a Poisson or Gamma function peaking at about 5 s. This simple linear framework is the cornerstone for making statistical inferences about activations in fMRI with the general linear model. The notion of using temporal basis functions to model evoked responses in fMRI was subsequently introduced²² and applied to event-related responses²³ (see also Lang and Zeger²⁴).

4.2.2 *Temporal Basis Functions*

Temporal basis functions are important because they provide a graceful transition between conventional multilinear regression models with one stimulus function per condition and FIR models with a parameter for each time point following the onset of a condition or trial type. Temporal basis functions offer useful constraints on the form of the estimated response that retain the flexibility of FIR models and the efficiency of single regressor models. In practice, the implementation of these constrained FIR models involves setting up stimulus functions that model expected neuronal changes (e.g., box-cars of epoch-related responses or spikes (delta functions) at the onset of specific events or trials). These regressors are then convolved with a set of basis functions that model the HRF, in some linear combination, and are assembled into the design matrix. The basis functions can be as simple as a single canonical HRF through to a series of delayed delta functions. The latter case corresponds to a FIR model proper and the coefficients are the impulse response function for the event or epoch in question. Selective averaging in event-related fMRI is mathematically identical to this limiting case.²⁵

The advantage of using temporal basis functions (as opposed to an assumed form for the HRF) is that one can model voxel-specific forms for hemodynamic responses²⁴ and formal differences (e.g., onset latencies) among responses to different sorts of events. The advantages of using basis functions over FIR models are that the parameters are estimated more efficiently and stimuli can be presented at any point in the interstimulus interval. The latter is very important because time-locking stimulus presentation and data acquisition gives biased sampling over peristimulus time and can lead to differential sensitivities, in multislice acquisition, over the brain.

4.3 *Statistical Inference and the Theory of Gaussian Fields*

Inferences using SPMs can be of two sorts depending on whether the area involved is known in advance. With an anatomically constrained hypothesis, about effects in a particular brain region, the uncorrected p value associated with the height or extent of that region in the SPM can be used to test the hypothesis. With an anatomically open hypothesis (i.e., a null hypothesis that there is no effect anywhere in the brain) a correction for multiple dependent comparisons is necessary. The theory of Gaussian fields provides a way of computing this corrected p value that takes into account the fact that neighboring voxels are not independent by virtue of smoothness in the original data. Provided the data are sufficiently smooth, the correction based on Gaussian field theory is less severe (i.e., is more sensitive) than a Bonferroni correction for the number of voxels.

The only assumptions underlying the use of Gaussian field theory are that: (i) the residual fields (but not necessarily the data) are a reasonable lattice approximation to an underlying Gaussian field; (ii) the fields have a twice differentiable autocorrelation function (a common misconception is that the autocorrelation function has to be Gaussian; it does not) and (iii) their multinormal correlation structure is wide sense stationary. The only way in which these assumptions can be violated is if the data are not smoothed (with or without subsampling of the data to preserve resolution) or the statistical

model is mis-specified and spatially coherent signals (e.g., global effects) end up in the residuals.

4.3.1 Anatomically Closed Hypotheses

When making inferences about regional effects (e.g., activations) in statistical maps, there is often some idea about where the activation should be. In this instance, a correction for the entire search volume is inappropriate. However, a problem remains in the sense that activations that are ‘near’ the predicted location should be considered even if they are not exactly coincident. There are two approaches to this: prespecify a small search volume and make the appropriate correction¹⁵ or use the uncorrected p value based on the spatial extent of the nearest cluster.²⁶ This probability is based on obtaining the observed number of voxels, or more, in a given cluster (conditional on that cluster existing) and can be calculated using distributional approximations from the theory of Gaussian fields.

4.3.2 Anatomically Open Hypotheses and Levels of Inference

To correct for the volume of brain analyzed, the SPM is subject to thresholding, using some height and spatial extent thresholds, and p values are derived that pertain to: (i) the number of activated regions (i.e., number of clusters above the height and volume threshold), known as *set-level inferences*; (ii) the number of activated voxels (i.e., volume) comprising a particular region, known as *cluster-level inferences*; and (iii) the p value for each voxel within that cluster, known as *voxel-level inferences*. These p values are corrected for the multiple dependent comparisons and are based on the probability of obtaining c , or more, clusters with k , or more, voxels, above a threshold u in an SPM of known or estimated smoothness.²⁷ This probability has a reasonably simple form and is derived using distributional approximations from the theory of Gaussian fields (see Figure 3 for details).

Set-level inference refers to the inference that the number of clusters comprising an observed activation profile is highly unlikely to have occurred by chance and pertains to the activation profile as characterized by its constituent regions. Cluster-level inferences are a special case of set-level inferences that obtain when the number of clusters is 1. Similarly, voxel-level inferences are special cases of cluster-level inferences that result when the cluster can be small (i.e., $k=0$). Using a theoretical power analysis²⁷ of distributed activations, it can be shown that set-level inferences are generally more powerful than cluster-level inferences and that cluster-level inferences are generally more powerful than voxel-level inferences. The price paid for this increased sensitivity is reduced localizing power: Voxel-level tests permit individual voxels to be identified as significant, whereas cluster and set-level inferences only allows clusters or sets of clusters to be so identified.

4.4 Experimental Design and Analysis

4.4.1 Cognitive Subtractions and Conjunctions

The tenet of cognitive subtraction and conjunction is that the difference between two tasks can be formulated as a separable cognitive or sensorimotor component and that the regionally specific differences in hemodynamic responses identify

the corresponding functionally specialized area. Early applications of subtraction range from the functional anatomy of word processing²⁸ to functional specialization in extrastriate cortex.²⁹ The latter studies involved presenting visual stimuli with and without some sensory attribute (e.g., color, motion, etc.). The areas highlighted by subtraction were identified with homologous areas in monkeys that showed selective electrophysiological responses to equivalent visual stimuli.

Cognitive conjunctions³⁰ can be thought of as an extension of the subtraction technique, in the sense that they combine a series of subtractions. In subtraction, a hypothesis pertaining to the activation in one task relative to another is tested. In conjunction analyses, several hypotheses are tested, asking whether all the activations, in a series of task pairs, are jointly significant. Consider the problem of identifying regionally specific activations caused by a particular cognitive component (e.g., object recognition). If a series of task pairs can be identified with differences that have only that component in common, then the region which activates in all the corresponding subtractions can be associated with the component in question. Conjunction analyses demonstrate this context-insensitive nature of regional responses. One important application of conjunction analyses is in multisubject fMRI studies where generic effects are identified as those that are conjointly significant in all the subjects studied (see below).

4.4.2 Parametric Designs

The premise behind parametric designs is that regional physiology will vary systematically with the degree of cognitive or sensorimotor processing. Examples of this approach include the positron emission tomographic (PET) experiments of Grafton et al., who demonstrated significant correlations between hemodynamic responses and the performance of a visually guided motor tracking task.³¹ On the sensory side, Price et al. demonstrated a remarkable linear relationship between perfusion in peri-auditory regions and frequency of aural word presentation.³² This correlation was not observed in Wernicke’s area, where perfusion appeared to correlate not with the discriminative attributes of the stimulus but with the presence or absence of semantic content. These relationships or ‘neurometric functions’ may be linear or nonlinear. Using polynomial regression, in the context of the general linear model, nonlinear relationships between stimulus parameters (e.g., stimulus duration or presentation rate) and evoked responses can be identified; this is usually achieved using a SPM{F}.¹⁹

The example provided in Figure 4 illustrates subtraction, conjunction, and parametric approaches to design and analysis. These data were obtained from a fMRI study of visual motion processing using radially moving dots. The stimuli were presented over a range of speeds using isoluminant and isochromatic stimuli. To identify areas involved in visual motion, a stationary dots condition was subtracted from the moving dots conditions (see contrast weights on the upper right). To ensure significant motion-sensitive responses, using both color and luminance cues, a conjunction of the equivalent subtractions was assessed under both viewing contexts. Areas V5 and V3a are seen in the ensuing SPM{T}. The responses in left V5 speak to a very compelling inverted ‘U’ relationship between speed and evoked response that peaks at around 8° s^{-1} . It is this sort of relationship that parametric designs try to characterize. Interestingly, the form of these speed-dependent

Figure 3 The theory of Gaussian fields. If an anatomical location is already suspected, inference can be based on the value of the statistic at the specified location in the SPM without correction. If, however, there was no anatomical constraint, then a correction for multiple dependent comparisons has to be made. These corrections are usually made using distributional approximations from the theory of Gaussian fields. This schematic deals with the most general case of n SPM{T} where the voxels all survive a common threshold t (i.e., a conjunction). The central probability, upon which all voxel-, cluster- or set-level inferences rest is the probability P of getting c or more clusters with k or more resels (resolution elements) above this threshold. By assuming that clusters behave like a multidimensional Poisson point process (i.e., the Poisson clumping heuristic) P is simply determined given that the distribution of c is Poisson with an expectation λ . The term λ is the product of the expected number of clusters of any size and the probability that any cluster will be bigger than k resels. The latter probability is shown using a form for a single Z-variate field constrained by the expected number of resels per cluster ($\langle \cdot \rangle$ denotes expectation or average). The expected number of resels per cluster is simply the expected number of resels in total divided by the expected number of clusters. The expected number of clusters is estimated with the Euler characteristic (EC) (effectively the number of blobs minus the number of holes). This estimate is, in turn, a function of the EC density for the statistic in question (with ν degrees of freedom) and the resel counts. The EC density is the expected EC per unit of D -dimensional volume of the SPM where the D -dimensional volume of the search space is given by the corresponding element in the vector of resel counts. Resel counts can be thought of as a volume metric that has been normalized by the smoothness of the SPM component fields expressed in terms of the full width at half maximum (FWHM). This is estimated from the determinant of the variance-covariance matrix of the first spatial derivatives $\mathbf{u}$ of the normalized residual fields $\mathbf{r}$. In this example, equations for a sphere of radius r are given. The term Φ denotes the cumulative distribution function for the subscripted statistic in question.

responses was similar using both stimulus types although luminance cues are seen to elicit a greater response. From the point of view of a factorial design, there is a main effect of cue (isoluminant versus isochromatic), a main (nonlinear) effect of speed, but no speed by cue interaction.

4.4.3 Factorial Designs

At its simplest, an interaction represents a change in a change. Interactions are associated with factorial designs where two or more factors are combined in the same experiment. The effect of one factor on the effect of the other is assessed by the interaction term. Factorial designs have a wide range of appli-

cations. An early application in neuroimaging examined physiological adaptation and plasticity during motor performance by assessing time by condition interactions.³³ Psychopharmacological activation studies are examples of factorial designs.³⁴ In these studies, cognitively evoked responses are assessed before and after a drug is taken. The interaction term reflects the modulatory drug effect on the task-dependent activation. Factorial designs have an important role in the context of cognitive subtraction and additive factors logic by virtue of being able to test for interactions, or ‘context-sensitive activations’ (i.e., to demonstrate the fallacy of ‘pure insertion’).³⁵ These interaction effects can sometimes be interpreted as the integration of the two or more (cognitive) processes or

Figure 4 The design matrix is shown as an image representation where contrasts are the vectors of contrast weights defining the linear compounds of parameters tested. The contrasts are displayed over the column of the design matrix that corresponds to the effects in question. The design matrix here includes condition-specific effects (box-cars convolved with a hemodynamic response function). Odd columns correspond to stimuli shown under isochromatic conditions and even columns model responses to isoluminant stimuli. The first two columns are for stationary stimuli and the remaining columns are for conditions of increasing speed. The final column is a constant term. The SPM{T} is a maximum intensity projection of the SPM{T} conforming to the standard anatomical space of Talairach and Tournoux.⁷ The T values here are the minimum T values from both contrasts, thresholded at $p=0.001$ uncorrected. The most significant conjunction is seen in the left V5. A plot of the condition-specific parameter estimates for this voxel is shown. The T value was 9.25 ($p<0.001$ corrected; see Figure 3)

as the modulation of one (perceptual) process by another being manipulated (see Figure 5).

5 A SIGNAL PROCESSING PERSPECTIVE

In this section we consider fMRI time series from a signal processing perspective with particular reference to frequency domain representations.

5.1 Temporal (serial) Autocorrelations and Efficiency

fMRI time series can be viewed as a linear admixture of signal and noise (Figure 6). Signal corresponds to neuronally mediated hemodynamic changes that can be modeled as a (non)linear convolution of some underlying neuronal process responding to changes in experimental factors. Noise has many contributions that render it rather complicated in relation to other neurophysiological measurements. These include neuronal and non-neuronal sources. Neuronal noise refers to neurogenic signal not modeled by the explanatory variables and with the same frequency structure as the signal itself. Non-neuronal components have both white (e.g., rf (Johnson) noise) and colored components (e.g., pulsatile motion of the brain caused by cardiac cycles and local modulation of the static magnetic field (B_0) by respiratory movement). These effects are typically low frequency or wide band (e.g., aliased cardiac-locked pulsatile motion). The superposition of all these components creates temporal correlations among the error terms in the statistical model (denoted by Σ in Figure 2) that can have a severe effect on sensitivity to experimental effects. Sensitivity depends upon the relative amounts of signal and noise and the efficiency of the experimental design. Efficiency is simply a measure of how reliable the parameter estimates are and can be defined as the inverse of the variance of a contrast of parameter estimates (see Figure 2). There are two important considerations arising from this perspective of fMRI time series: the first pertains to optimal experimental design and the second to optimum (de)convolution of the time series to obtain the most efficient parameter estimates.

5.1.1 The Hemodynamic Response Function and Optimum Design

As noted above, an LTI model of neuronally mediated signals in fMRI suggests that, whatever the frequency structure of experimental variables, only those that survive convolution with the HRF can be estimated with any efficiency. By convolution theorem, the experimental variance should, therefore, be designed to match the transfer function of the HRF. The corresponding frequency profile of this transfer function is shown in Figure 7 (solid line in the upper left panel). It is clear that frequencies around 0.03 Hz are optimal, corresponding to periodic designs with 32-s periods (e.g., 16-s epochs). Generally the first objective of experimental design is to comply with the natural constraints imposed by the HRF and to ensure that experimental variance occupies these intermediate frequencies.

5.1.2 The Noise Spectrum: Efficiency and Bias

The noise spectrum is a complicated but important area. Conventional signal processing approaches dictate that whitening the data engenders the most efficient parameter estimation. This corresponds to filtering with a convolution matrix S (see Figure 2) that is the inverse of the intrinsic convolution matrix K ($KK^T = \Sigma$). There are, however, two fundamental problems with this: one generally does not know the intrinsic correlations Σ and even if they were known for any given time series, adopting the same assumptions for all voxels will lead to bias and loss of efficiency because each voxel has a different temporal autocorrelation structure (e.g., brainstem voxels will be subject to pulsatile effects; ventricular voxels will be subject to cerebrospinal fluid flow artifacts; white matter voxels will not

Figure 5 Assessing an interaction using an event-related design: attentional modulation of V5 responses. Subjects viewed stationary monochromatic stimuli that occasionally changed color and moved at the same time. These compound events were presented under two levels of attentional set (attention to color and attention to motion). The event-related responses are modeled, in an attention-specific fashion, by the first four regressors (delta functions convolved with a hemodynamic response function and its derivative) in the design matrix on the right. The simple main effects of attention are modeled as similarly convolved box-cars. The interaction between attentional set and visually evoked responses is simply the difference in evoked responses under both levels of attention and is tested for with the appropriate contrast (upper right). Only the first 256 rows of the design matrix are shown. The most significant modulation of evoked responses under attention to motion was seen in left V5 (insert). The fitted responses and their standard errors are shown on the left as functions of peristimulus time

be subject to neurogenic noise). The first problem is highlighted in Figure 6. Here the residuals from a long (1000 scan, $TR=1.7$ s) time series were used to estimate the spectral density and associated autocorrelation functions (where one is proportional to the Fourier transform of the other) using the Yule-Walker method with an autoregression order of 32. Estimates using a commonly assumed AR(1) model³⁶ and a modified $1/f$ model³⁷ are also shown. The AR(1) is inadequate and fails to model long-range correlations (i.e., low frequencies). The $1/f$ model shown here is an extremely good approximation (even more so since the parameters of this model were not estimated using the data but taken from the literature). However, the $1/f$ model fails to model the short-term correlation structure as well as it could. The discrepancy between the assumed and actual form of temporal correlations means that, when the data are whitened in accord with the assumed models, the standard error of the parameter estimates (i.e., their variance) is over-[AR(1)] or under-($1/f$) estimated. This leads directly to bias in the ensuing statistics (the T statistic is simply the quotient of the contrast and its estimated standard error; see Figure 2). The effect is not trivial and can easily reach 50% for common experimental epoch- and event-related designs. Expected bias is computed using the intrinsic and assumed autocorrelations and

the expression for the expected estimate of parameter estimate variance in Figure 2.

5.2 Temporal Filtering and the Bias Problem

One solution to the ‘bias problem’ involves ‘regularizing’ the temporal autocorrelation structure by filtering.¹⁸ This effectively imposes a structure on the temporal autocorrelations that renders the difference between the assumed and actual correlations less severe. Although less efficient, the ensuing inferences are less biased and more robust. The loss of efficiency can be minimized by appropriate experimental design and choosing a suitable filter S . The example in Figure 7 combines the HRF and high-pass filtering at 1/64 Hz, which, when applied to the time series, markedly reduces the differences among the various models assumed for the autocorrelations (compare Figure 6b with Figure 7b).

Not only does appropriate temporal filtering reduce bias engendered by mis-specification of the intrinsic correlations but it also addresses the nonstationary nature of serial correlations over voxels. Figure 7c,d shows bias over 512 voxels using a voxel-specific estimate for the intrinsic correlations and the

Figure 6 Spectral densities (a) and corresponding autocorrelation functions (b) for the residual terms of a fMRI time series for an AR(32) model estimated using the Yule-Walker method (this is taken to be the closest to an ‘empirical’ estimate), an AR(1) model estimate using the same method, and a model of the form $(q/f+1)$ where f is frequency in hertz and $q=0.0178$ (line $1/f$)

average over all voxels for the assumed structure. Without filtering, the biases (solid bars) range from 80 to 150%. With filtering (open bars) they are reduced substantially. The effect on efficiency is shown in Figure 7d. It is interesting to note that temporal autocorrelations render the efficiency very variable over voxels (by nearly an order of magnitude). This is important because it means that fMRI is not homogeneous in its sensitivity to evoked responses from voxel to voxel.

5.3 Spatially Coherent Confounds and Global Normalization

Implicit in the use of high-pass filtering is the removal of low-frequency components that can be regarded as confounds. Other important confounds are signal components that are artifactual or have no regional specificity. These are referred to as global confounds and can have physiological causes (e.g., global perfusion changes mediated by changes in partial pressure of CO_2) and nonphysiological causes (e.g., transmitter power calibration, B_1 coil profile and receiver gain). The latter will

generally scale the signal before the MRI sampling process. Other nonphysiological effects may have a nonscaling effect (e.g., Nyquist ghosting or movement-related effects). Instrumentation effects that scale the data are treated by a global normalization by proportional scaling using the whole brain mean. Spatially coherent confounds will, however, still persist, and a more sensitive statistical model obtains when these can be identified and modeled.

5.4 Nonlinear System Identification Approaches

So far we have only considered LTI models and first-order HRFs. Another signal-processing perspective is provided by nonlinear system identification.³⁸ This section considers nonlinear models as a prelude to the next section on event-related fMRI where nonlinear interactions among evoked responses impose constraints on experimental design and analysis.

We have described an approach to characterizing evoked hemodynamic responses in fMRI based on nonlinear system identification, in particular the use of Volterra series.³⁹ The approach employed enables *Volterra kernels* to be estimated that describe the relationship between stimulus presentation and the hemodynamic responses that ensue. Volterra series are essentially high-order extensions of linear convolution or FIR models. These kernels, therefore, represent a nonlinear characterization of the HRF that can model the responses to stimuli in different contexts and interactions among stimuli. In the context of fMRI, the kernel coefficients can be estimated by using a second-order approximation to the Volterra series to reformulate the problem in terms of a general linear model and by expanding the kernels in terms of temporal basis functions. This allows the use of the standard techniques described above to estimate the kernels (Figure 8) and to make inferences about their significance on a voxel-specific basis using SPMs.

One important manifestation of the nonlinear effects, captured by the second-order kernels, is a modulation of stimulus-specific responses by preceding stimuli that are proximate in time. This means that responses at high-stimulus presentation rates saturate and, in some instances, show an inverted U behavior (see Figure 9a). This behavior appears to be specific to BOLD (blood oxygenation level-dependent) effects (as distinct from evoked changes in cerebral blood flow) and may represent a hemodynamic ‘refractoriness’. This effect has important implications for event-related fMRI.

6 EPOCH- AND EVENT-RELATED fMRI

A crucial distinction in fMRI is that between epoch- and event-related designs. An important issue in event-related fMRI is the choice of interstimulus interval, more precisely termed stimulus onset asynchrony (SOA). The SOA, or the distribution of SOA values, is a critical factor in experimental design and is chosen, subject to some constraints, to maximize the efficiency of response estimation. The constraints on the SOA clearly depend upon the nature of the experiment but are generally satisfied when the SOA is small and derives from a random distribution. Rapid presentation rates allow for the maintenance of a particular cognitive or attentional set, decrease the latitude that the subject has for engaging alternative strategies (incidental processing), and allows the

Figure 7 Bias and filtering: the effect of smoothing on bias when estimating the variance of contrasts. (a) The spectral density of the hemodynamic response function (a mixture of two gamma functions) (solid line) and after high-pass filtering at 1/64 Hz (broken line). The corresponding filter in time is shown in the insert. (b) The autocorrelation functions predicted on the basis of the three models shown in Figure 6 after filtering with the kernel in the insert. Compare these autocorrelation functions with those in Figure 6. The differences are now ameliorated. (c,d) The distribution of bias (c) and efficiency (d) over voxels using an AR(8) model to estimate serial correlations at each voxel and assuming a stationary autocorrelation structure over voxels. Distributions are shown with (white bars) and without (filled bars) filtering. Note how filters reduce bias (at the expense of reduced efficiency). Bias is expressed as the ratio of estimated to actual contrast estimate variance and should, ideally, be unity. Efficiency is the inverse of the actual contrast estimate variance

integration of event-related paradigms using fMRI and electrophysiology. Random SOAs ensure that preparatory or anticipatory factors do not confound event-related responses and ensure a uniform context in which events are presented. These constraints indicate the well-documented advantages of event-related fMRI over conventional blocked designs.^{23,40–42}

In general, the explanatory variables are created by convolving a set of delta functions, indicating the presence of a particular event, with a small set of basis functions that model the hemodynamic response to those events.²³ A special case of this general approach obtains when the basis functions are delta functions placed at a discrete set of peristimulus times. This special case corresponds to selective averaging²⁵ and requires stimulus presentation and data acquisition to be synchronized (which in general is not a good idea). We find the most useful basis set to be a canonical HRF and its derivatives with respect to its parameters (e.g., latency and dispersion). The nice thing about this approach is that it partitions differences among evoked responses into differences in magnitude, latency, or dispersion that can be tested for using specific contrasts and the SPM{T} (see Friston et al.⁴³ for details).

6.1 Stochastic and Deterministic fMRI Designs

fMRI designs can vary over a large number of parameters. In order to compare the efficiency of different designs it is use-

ful to have some common framework that accommodates them all. The efficiency can then be examined in relation to the parameters of the design. Any design can be ‘stochastic’ or ‘deterministic’. In stochastic designs, the probabilities of an event occurring must be specified at all times those events could occur.⁴⁴ In deterministic designs, the occurrence probability is unity and the design is completely specified by the times of stimulus presentation or trials. The distinction between stochastic and deterministic designs pertains to how a particular realization or stimulus sequence is created. The efficiency afforded by a particular event sequence is a function of the event sequence itself, and not of the process generating the sequence (i.e., deterministic or stochastic). With a stochastic design, the design matrix X , and associated efficiency, are random variables. However, for finite length sequences, the expected efficiency over an infinite number of realizations of X is easily computed, as now described. In the framework considered here the probability p of any event occurring is specified at each time it could occur (i.e., every SOA_{min}). This gives the vector p with an element for every SOA_{min} . This formulation shows the distinction between ‘stationary’ stochastic designs, where the occurrence probabilities are constant, and nonstationary or ‘dynamic’ stochastic designs, where they change over time. For deterministic designs, the elements of p are 0 or 1, the presence of a 1 denoting the occurrence of an event. An example of p might be the box-cars used in conven-

Figure 8 Volterra kernels h_1 and h_2 based on parameter estimates from a voxel in the left superior temporal gyrus at -56 , -28 , and 12 mm. These kernel estimates were based on a study in a single subject of aural word presentation at different rates (from 0 to 90 words per minute) using a second-order approximation to a Volterra series expansion modeling the observed hemodynamic response to stimulus input (a delta function for each word). These kernels can be thought of as a characterization of the second-order hemodynamic response function. (a) The first-order kernel (h_1) represents the (first-order) component usually presented in linear analyses. (b) The second-order kernel (h_2) is presented in image format. The color scale is arbitrary; white is positive and black is negative. The insert represents $[-h_1 \cdot h_1^T]$, the second-order kernel that would be predicted by a simple model that involved convolution with h_1 followed by some nonlinear scalar function

tional block designs. Stochastic designs of the sort proposed by Dale and Buckner correspond to a vector of identical values and are therefore stationary in nature.²⁵ Stochastic designs with temporal modulation of occurrence probability correspond to probability vectors with time-dependent probabilities varying between 0 and 1. With these probabilities, the expected design matrices and expected efficiencies can be computed. The nice

thing about this formulation is that by setting the mean of the probabilities to a constant, different deterministic and stochastic designs can be compared given the same number of events (or equivalently same mean SOA). Some common examples are given in Figure 9b for an SOA_{min} of 1 s and 32 expected events or trials over a 64-s period (except the fixed-SOA deterministic example with four events). It can be seen that the least efficient is a fixed-interval deterministic design (despite the fact that the SOA is roughly optimal for this class), whereas the most efficient is a block design. A slow modulation of occurrence probabilities gives high efficiency while retaining the advantages of stochastic designs and may represent a very useful compromise between the high efficiency of block designs and the psychological benefits and latitude afforded by stochastic designs.

6.2 What is the Minimum Stimulus Onset Asynchrony?

The minimum SOA can be found using Volterra series (see section 5.4) and the results of a typical analysis are given in Figure 9a. This represents the average response, integrated over a 32-s train of stimuli as a function of SOA within that train. These responses were based on kernel estimates using data from a voxel in the left posterior temporal region of a subject obtained during the presentation of a single word at a variety of rates. The solid line represents the estimated response and shows a clear maximum at just less than 1 s. The points represent estimates based on empirical data from the same experiment. The broken line shows the expected response in the absence of nonlinear effects (i.e., those predicted by setting the second-order kernels to zero). It is clear that nonlinearities become important at around 2 s leading to an actual diminution of the integrated response at SOA values less than a second. The implications of these data are that SOAs should not really fall much below 1 s and at short SOA values the assumptions of linearity are violated. It should be noted that these data pertain to single-word processing in the auditory association cortex. More ‘linear’ behaviors may be expressed in primary sensory cortex,²⁵ where the feasibility of using SOA_{min} values as low as 500 ms has been demonstrated even when sampling at a lower rate (e.g., $TR=1$ s).⁴⁵

6.3 Stationary Stochastic Designs and Efficiency

In this section we consider why, in some instances, a very short average SOA is best whereas in others a longer SOA is more appropriate. Here we deal explicitly with multiple trial types⁴³ and define the trial onset asynchrony (TOA) as the interval between onsets of a particular trial type. The best TOA depends upon the nature of the characterization of evoked responses that is required. For any given event type, the associated p value determines the average or expected TOA for that event type. This is simply $SOA_{min}/\langle p \rangle$, where $\langle p \rangle$ is the mean probability for the each trial type. By varying p and SOA_{min} the most efficient design can be identified for examining evoked responses themselves or differences among evoked responses. These two situations are depicted in Figure 9c. It is immediately obvious that for both sorts of effect very small SOA values are optimum. However, the optimum occurrence

Figure 9 (a) Plot of integrated responses over a 32-s stimulus train as a function of stimulus onset asynchrony (SOA): estimates based on a nonlinear convolution model (see Figure 8) (—); averages of empirical data from the presentation of actual stimulus trains (●); responses expected in the absence of second-order effects (---). (b) A comparison of some common (and some untried) stationary and nonstationary stochastic designs. The left-hand column is a graphical representation of the occurrence probabilities p expressed as a function of time (seconds). The efficiency of each design is shown along the ordinate assuming an $SOA_{\min}$ of 1 s and a time series of 64 s for a single trial-type design. The expected number of events (i.e., the mean value of p) was 0.5 in all but the first, corresponding to an expected trial onset asynchrony of 2 s or 32 events. (c) Efficiency in a stationary stochastic design with two event types each presented with probability p every $SOA_{\min}$. The upper graph is for a contrast testing for the response evoked by a particular trial type and the lower graph is for a contrast testing for differential responses

probabilities are not the same. More infrequent events (corresponding to a smaller p) are required to estimate efficiently the responses themselves. This is equivalent to treating the baseline or control condition as any other condition (i.e., by including null events, with equal probability, as further event types).

Therefore, by making the probability of null events and all other events equal to $1/(n+1)$, where n is the number of event types, we get a mean TOA of $(n+1)SOA_{\min}$. Such designs result in optimal and equivalent efficiency for all comparisons (within stationary stochastic designs).

7 INFERENCES ABOUT SUBJECTS AND POPULATIONS

For a given group of subjects, there is a fundamental distinction between saying that the average response is significant in relation to the variability of the subjects' responses and saying that there is a significant response in relation to the variability *about* those subject-specific responses. This distinction relates directly to the difference between 'fixed' and 'random' effect analyses. The following example tries to make this clear. Consider what would happen if we scanned six subjects during the performance of a single task, relative to a baseline. We then constructed a statistical model where task-specific effects were modeled separately for each subject. Unknown to us, only one of the subjects activated a particular brain region. When we examine the contrast of parameter estimates assessing the mean activation over all the subjects, we see that it is greater than zero by virtue of this subject's activation. Furthermore, because that model fits the data extremely well (modeling no activation in five subjects and a substantial activation in the sixth) the error variance, on a scan-to-scan basis, is small and the T statistic is very significant. Can we then say that the group shows an activation? We can say, quite properly, that the mean group response embodies an activation but clearly this does not constitute an inference that the group's response is significant (i.e., that this sample of subjects shows a consistent activation). The problem here is that we are using the scan-to-scan error variance and this is not necessarily appropriate for an inference about group responses. In order to make the inference that the group showed a significant activation, the variability in activation effects must be assessed from subject to subject (using the contrast of parameter estimates for each subject). This variability now constitutes the proper error variance. In this instance, the variance of these six measurements would be large relative to their mean, and the corresponding T statistic would not be significant.

The distinction between the two approaches above relates to how the appropriate error variance is calculated. The first represents a fixed-effect analysis and the second a random-effect analysis. In the former, the error variance is estimated on a scan-to-scan basis, assuming that each scan represents an independent observation (ignoring serial correlations). Here the degrees of freedom are essentially the number of scans (minus the rank of the design matrix). Conversely, in random-effect analyses, the appropriate error variance is based on the activation from subject to subject where the effect per se constitutes an independent observation and the degrees of freedom fall dramatically to the number of subjects. The term random-effect indicates that we have accommodated the randomness of differential responses by comparing the mean activation to the variability in activation from subject to subject. Both analyses are perfectly valid but only in relation to the inferences that are being made.

7.1 Random Effects Analyses

The implementation of random effect analyses in SPM is fairly straightforward and involves taking the contrasts of parameters estimated from a first-level (fixed-effect) analysis and entering them into a second-level (random-effect) analysis. This ensures that there is only one observation (i.e., contrast)

per subject in the second-level analysis and that the error variance is computed using the subject-to-subject variability. The nature of the inference made is determined by the contrasts entered into the second level (Figure 10). The second-level design matrix simply tests the null hypothesis that the contrasts are zero (and is usually a column of ones implementing a single sample T test).

7.2 Conjunction Analyses and Population Inferences

There is an alternative approach based on fixed-effect analyses that allows qualitative inferences about population effects. This approach uses conjunctions (as described in Section 4.4.1). Conjunction analyses in the context of multisubject fMRI studies allows an inference to be made at the level of the fixed-effect analysis based on the null hypotheses of no activation in any of the subjects studied, and allows an inference to be made at a second level about the population in terms of the proportion of the population that is likely to show the regionally specific effect. If, for any given contrast, a conjunction of effects over n subjects can be established using a test with a specificity of α and sensitivity β , the probability, under the null hypotheses, of this occurring by chance can be expressed as a function of γ , the proportion of the population (from which the subjects were sampled) with the effect (see the equation in Figure 10). Now this probability has an upper bound (α_c), corresponding to a critical proportion (γ_c), which is realized when the (generally unknown) sensitivity is one. In other words, under the null hypothesis (at the second level) the proportion of the population evidencing this effect is less than or equal to γ_c and the probability of getting a conjunction over n subjects is equal to, or less than, α_c (where $\alpha_c > \alpha$). In short, a conjunction allows one to say, with a specificity of α_c , that more than γ_c of the population show the effect in question. Formally, we can view this analysis as a conservative $100(1-\alpha_c)\%$ confidence region for the unknown parameter γ . Specifically, the confidence region is $\gamma \geq \gamma_c$ if the conjunction occurs, and all values of γ if it does not. This approach retains the sensitivity of fixed-effect analyses yet still provides qualitative inferences about the population. These inferences can be construed as statements about how typical the effect is without saying that it is necessarily present in every subject.

In practice, a conjunction analysis of a multisubject/session fMRI study comprises the following steps: (i) A design matrix is constructed where the explanatory variables pertaining to each experimental condition are replicated for each session. This subject-separable design matrix implicitly models session by condition interactions (i.e., different condition-specific responses among sessions). (ii) Contrasts are then specified that test for the effect of interest in each session to obtain a set of SPM{T}. (iii) These SPM{T} are thresholded at u (corresponding to some uncorrected specificity α) and combined to give a SPM of the conjunction. The ensuing SPM has two equivalent interpretations: first it represents the intersection of the excursion sets, defined by u , of the subject-specific SPM{T}; second, it is an SPM of the minimum value of the T values at u . (iv) The corrected (for search volume) and uncorrected p values associated with each voxel are now computed as described in Figure 2. These p values provide for inferences about the particular subjects studied. However, because we have demonstrated regionally specific conjunctions, we can

Figure 10 Schematic illustrating the implementation of random-effect and conjunction analyses for population inference. The lower right graph shows the probability of obtaining a conjunction, conditional on a certain proportion γ of the population expressing the effect in question, for a test with specificity of $\alpha=0.05$, (corresponding to a Z-variate threshold of 1.64) at several sensitivities ($\beta=1, 0.9, 0.8$, and 0.6). The critical specificity for population inferences $\alpha_{critical}$ and the associated proportion of the population $\gamma_{critical}$ are denoted by the thin lines. This probability $p(n)$ is given by the function of α , β , and γ

now proceed to make an inference (at a second level) about the population from which these subjects came using the confidence region approach described above.

8 EFFECTIVE CONNECTIVITY AND FUNCTIONAL INTEGRATION

There is a necessary relationship between approaches to characterizing functional integration and multivariate analyses because the latter are necessary to model interactions among brain regions. Multivariate approaches can be divided into those that are inferential in nature and those that are data led or exploratory. Most are based on the singular value or eigen decomposition of the between-voxel covariances in a fMRI time series.

8.1 Eigen-image Analysis and Related Approaches

Voxel-based PCA of neuroimaging time series can be used to characterize distributed brain systems implicated in sensorimotor, perceptual, or cognitive processes.⁴⁶ These distributed

systems are identified with principal components or eigenimages that correspond to spatial modes of coherent brain activity. This approach represents one of the simplest multivariate characterizations of functional neuroimaging time series and falls into the class of exploratory analyses. PCA or eigen-image analysis generally uses SVD to identify a set of orthogonal spatial modes that captures the greatest amount of variance, expressed over time. As such, the ensuing modes embody the most prominent aspects of the variance-covariance structure of a given time series. Noting that the covariances among brain regions is equivalent to functional connectivity renders eigenimage analysis particularly interesting because it was one of the first ways of addressing functional integration (i.e., connectivity) in the human brain. Subsequently, eigen-image analysis has been elaborated in a number of ways including CVA⁴⁷ and multidimensional scaling.⁴⁸ CVA was introduced in the context of ManCova (multiple analysis of covariance) and uses the generalized eigen-vector solution to maximize the variance that can be explained by some explanatory variables relative to error. CVA can be thought of as an extension of eigen-image analysis that refers explicitly to some explanatory variables and allows for statistical inference.

Figure 11 Characterization of effects of V2 inputs on V5 and the modulation of these effects by posterior parietal cortex (PPC) using simulated inputs at different levels of PPC activity. The broken lines represent estimates of V5 responses when PPC activity is 0, according to a second-order Volterra model with inputs based on the activity in V2, PPC, and the pulvinar (all normalized to zero mean and unit standard deviation). The simulated input, from V2, corresponded to a square wave of 500 ms duration convolved with a hemodynamic response function. The solid curves represent the same response when PPC activity is one. It is evident that V2 has an activating effect on V5 and that PPC increases the responsiveness of V5 to these inputs. The insert shows all the voxels in V5 that evidenced a modulatory effect ($p < 0.05$ uncorrected). These voxels were identified by thresholding SPMs of the F statistic testing for the contribution of second-order kernels involving V2 and PPC while treating all other components as confounds. Results for three subjects are shown. Subjects were studied with fMRI under identical stimulus conditions (visual motion subtended by radially moving dots while manipulating the attentional component of the task (detection of velocity changes))

In relation to fMRI data⁴⁹ eigen-image analysis is generally used as an exploratory device to characterize coherent brain activity. These variance components may, or may not, be related to experimental design, and endogenous coherent dynamics have been observed in the motor system.⁵⁰ Despite its exploratory power, eigen-image analysis is fundamentally limited for two reasons. First, it offers only a linear decomposition of any set of neurophysiological measurements and, second, the particular set of eigen-images or spatial modes obtained are uniquely determined by constraints that are biologically implausible. These aspects of PCA represent inherent limitations on the interpretability and usefulness of eigen-image analysis of biological time series. These observations have motivated the exploration of nonlinear PCA and neural network approaches to imaging time series.⁵¹

Two other important approaches deserve mention. The first is ICA, which uses entropy maximization to find, using iterative schemes, spatial modes or their dynamics that are approximately independent. This is a stronger requirement than orthogonality in PCA and involves removing high-order correlations among the modes (or dynamics). It was initially introduced as spatial ICA in which the independence constraint was applied to the modes (with no constraints on their temporal expression).⁵² More recent approaches use, by analogy with magneto and electrophysiological time series analysis, temporal ICA where the dynamics are enforced to be independent. In fMRI, this requires an initial dimension reduction (usually using conventional eigen-image analysis). Finally, there has been a considerable interest in cluster analysis. Con-

ceptually, this can be related to eigen-image analysis through multidimensional scaling and PCA. In cluster analysis, voxels in a multidimensional scaling space are assigned belonging probabilities to a small number of clusters, thereby characterizing the temporal dynamics (in terms of the cluster centroids) and spatial modes (defined by the belonging probability for each cluster). These approaches eschew many of the unnatural constraints imposed by eigen-image analysis and can be a very useful exploratory device.

8.2 Functional and Effective Connectivity

Imaging neuroscience has firmly established functional specialization as a principle of brain organization in humans; however, the functional integration of specialized areas has proven more difficult to assess. Functional integration is usually inferred on the basis of correlations among measurements of neuronal activity.⁵³ Functional connectivity has been defined as correlations between remote neurophysiological events.⁴⁶ However, correlations can arise in a variety of ways. For example, in multiunit electrode recordings they can result from stimulus-locked transients evoked by a common input or reflect stimulus-induced oscillations mediated by synaptic connections.⁵⁴ Integration within a distributed system is usually better understood in terms of effective connectivity; this refers explicitly to the influence that one neural system exerts over another, either at a synaptic (i.e., synaptic efficacy) or population level. It has been proposed that 'the [electro-

physiological] notion of effective connectivity should be understood as the experiment- and time-dependent, simplest possible circuit diagram that would replicate the observed timing relationships between the recorded neurons'.⁵⁵ This indicates two important points: effective connectivity is dynamic (i.e., activity and time dependent), and it depends upon a model of the interactions. The models employed in functional neuroimaging can be grouped as those based on regression models⁵⁶ or those based on structural equation modeling (i.e., path analysis).⁵⁷

8.3 Characterizing Nonlinear Coupling among Brain Areas

Linear models of effective connectivity assume that the multiple inputs to a region are linearly separable. This assumption precludes activity-dependent connections that are expressed in one sensorimotor or cognitive context and not in another. The resolution of this problem lies in adopting nonlinear models that include interactions among inputs. These interactions can be construed as a context- or activity-dependent modulation of the influence that one region exerts over another, where that context is instantiated by activity in further brain regions exerting modulatory effects. These nonlinearities can be introduced into structural equation modeling using so-called 'moderator' variables that represent the interaction between two regions in causing activity in a third.⁵⁸ From the point of view of regression models, modulatory effects can be modeled with nonlinear input-output models and, in particular, with the Volterra formulation described above. In this instance, the inputs are not stimuli but activities from other regions. Because the kernels are high order they embody interactions over time and among inputs. The influence of one region j on another i can therefore be divided into two components: the direct influence of j on i irrespective of the activities elsewhere, and an activity-dependent component that represents an interaction with inputs from the remaining regions. The example provided in Figure 11 addresses the modulation of visual cortical responses by attentional mechanisms and the mediating role of activity- or context-sensitive changes in effective connectivity.⁵⁹ Figure 11 shows a characterization of this modulatory effect in terms of the increase in V5(MT) responses to a simulated V2 input when posterior parietal activity is zero (broken line) and when it is high (solid lines). This sort of result suggests that parietal activity may be a sufficient explanation for attentional modulation of visually evoked extrastriate responses.⁶⁰

Image Quality and Perception

Brian S. Worthington

University of Nottingham, Nottingham, UK

Image quality is an elusive concept; a perfect image would reflect its underlying physical counterpart in all respects. In practice all clinical images fall short of this and provide less than complete information about their underlying substrate. They have physical limitations, which can be expressed in terms of such measures as signal-to-noise ratio, spatial resolution and contrast, and these depend on the performance of the imager, the display system and choice of imaging protocol; they are contaminated by noise and artifacts and furthermore the information they contain has to be abstracted and interpreted by a human observer.

Vision is central to radiology yet our perception of images because it occurs unconsciously, without effort, is all too often taken for granted. In reality human observers have significant physiological and cognitive limitations to their performance, and this has important implications in reporting errors and our efforts to reduce them.

1 INTRODUCTION

The totality of MRI scans which can be derived from any part of the human body represents the set of mappings of the spatial distribution of one or more of its properties. The great diversity of structures and pathological changes which are of relevance in radiological diagnosis imposes widely differing requirements for such images. In the detection of a microadenoma of the pituitary, for example, high spatial resolution is a prerequisite whilst, in the detection of intracranial hemorrhage, sensitivity to small tissue contrast differences is required. Any practical definition of magnetic resonance image utility must take account of the purpose for which the images are to be used; furthermore, in comparing the performance of different MRI scanners, any assessment must take account of the effectiveness with which the images generated can be used for their intended task. The design and construction of the scanner and especially the performance characteristics of such basic components as the magnet and gradient assembly set limits to the fundamental quality of data which are collected during imaging. It cannot always be assumed, however, that the quality of the final displayed image will faithfully reflect the quality of these collected data; appropriate choice of the level and width of the gray scale is necessary, for example, to ensure conspicuity of all clinically relevant features.

When radiologists speak of interpreting a set of MRI scans they dismiss in a phrase an act of enormous complexity which is being carried out by less than perfect observers. It is a matter of concern to all of them, that no matter how conscientiously they carry out their task errors occur and differences are found between the opinion of experienced radiologists as to the pre-

sence or otherwise of ostensibly relevant features in a given set of images. If one assumes adequate image quality and optimum viewing conditions then one must look elsewhere for an explanation of these apparent lapses and variations; consideration has to be given to the possibility that these arise from differences in the performance of observers in analyzing the complexity embodied in the image structure.

2 THE RADIOLOGICAL REPORTING TASK

The radiological reporting task contains several parts; detection, classification, and additional observations of clinical relevance. Detection involves identification of relevant features in a particular image set which then allows it to be classified, that is, assigned to one of a number of categories, the simplest being the binary decision of whether it is normal or abnormal. The radiologist makes an involuntary selection of features in an image, rejecting others as insignificant; unrelated contours are disregarded whilst other image elements are associated in a meaningful way. This process of abstraction from the overall background of an image, so rich in information, is perhaps the least understood and yet most important part of the diagnostic process; it occurs spontaneously on the part of the observer, its successful performance is unquestionably related to training and experience, and it is, in all probability, the single most important source of error.

The identification of the disease process underlying any abnormality is what constitutes the process of making a diagnosis, and whilst this is necessary for management, it may not be sufficient in itself to ensure that this is entirely appropriate. In the case of a malignant tumor, for example, one also needs to know the extent of spread in order to plan treatment. MRI like other techniques is applied after a history has been taken from a patient and a physical examination carried out. Its purpose is to reduce diagnostic uncertainty which may relate to the presence, type or extent of a disease process. In striving to achieve a diagnosis with MRI, it may be that we can only at best indicate that some abnormality is present without being able to characterize it. More frequently, taking into account the clinical picture, we can place an abnormality within a generic category of diagnosis, as with the identification of a tumor in the cerebellopontine angle cistern. Further features may permit tissue characterization to a degree where it is possible to make a specific diagnosis. Over and above its diagnostic capabilities MRI has proved invaluable in providing information which facilitates the planning of surgical operations.

In order to provide the maximum information from which an accurate diagnosis can be made so as to guide patient management, an appropriate set of images must have been generated.

3 THE ACQUISITION OF APPROPRIATE IMAGE SETS

The outstanding attribute of MRI is its ability to provide a substantially greater tissue contrast than has hitherto been available. This reflects the multiplicity of intrinsic tissue parameters which determine the MRI signal and their dynamic range. The complex user-controllable interdependence of these parameters

has profound effects on the signal-to-noise ratio, spatial resolution, image contrast and total examination time. Before selecting a protocol for a given examination, careful thought must be given to the possible prospective diagnosis so that appropriate choice of pulse sequence, field-of-view, matrix size, and number and thickness of slices is made to best accomplish demonstration of the suspected pathology in an acceptable time frame.¹ It has to be recognized that there is typically no single optimal set of parameters to achieve this objective and that the repertoire of possibilities is constantly being refined and extended as the knowledge base of clinical MRI expands.

Once the data have been acquired they are stored in a numerical matrix which represents relative signal intensities. The dynamic range of this data is far greater than can be encompassed in a tonal range of gray scale levels distinguishable by a human observer. In order, therefore, to facilitate interrogation of the whole data set, it is viewed at different gray scale window widths around a central level. Even when an appropriate protocol is chosen for a given pathology its presence may not be recognized; furthermore, early pathological changes may incorrectly be suspected in images which are in fact normal. There are several factors which contribute to such incorrect categorization of images. Noise, which occurs in the process of data acquisition, may mask the presence of relevant signal. Artifacts due to the inadequacy of data underlying image formation may simulate a lesion. Inappropriate display characteristics may lead to a lesion being overlooked and, finally, one has to consider the limitations of the human observer carrying out the task.

4 THE PERFORMANCE CHARACTERISTICS OF THE HUMAN VISUAL SYSTEM: IMPLICATIONS FOR IMAGE APPRAISAL

In order to analyze adequately the complexity embedded in the image structure, information which is transmitted through the display medium, be it film or a monitor, must match so far as possible the performance characteristics of the human visual system.

There is now convincing evidence that two separate stages are involved in the examination of visual displays, referred to as the preattentive and attentive phases by Julesz.² A display is examined holistically during the first glimpse, and this leads to the detection of features within the stimulus which allow a distinction to be made between 'figure and ground'. This has been shown to depend critically on simple local patterns of texture, the individual elements of which are referred to as textons. The methodology to investigate this phase of vision has been the use of tachistoscopic displays which have revealed the surprising level of information which can be assimilated in an exposure time as short as 100 milliseconds. Another approach has been to examine the statistical properties of artificial textural patterns which can and cannot be immediately segregated on visual inspection.

The second, or attentive phase of vision is where the display is serially examined using eye movements. During the individual fixations information is processed not just from the foveal area but a larger area around the fovea subtending approximately 6° of arc which Mackworth³ has called the useful field-

of-view. Of relevance to analysis of images is the demonstration that the density of irrelevant items in the display influences the size of this area and also that as the foveal load increases, the size of this area shrinks, although this effect can be mitigated to some extent with experience.

The spatial frequency model of vision due to Campbell and Robson⁴ provides us with a clear appreciation of the physiological constraints to vision and provides the rationale for the use of a number of strategies to improve our assimilation of relevant information contained in MRI scans. Using as a test object a grating of light and dark bars whose intensity varies sinusoidally across the stimulus, the contrast sensitivity of the human visual system has been measured at different spatial frequencies and reveals that the highest sensitivity to low contrast is at 3 cycles per degree with a response up to 50 cycles per degree but only at very high contrast. There is electrophysiological evidence to support the hypothesis that the visual system contains several independent channels each tuned to a narrow band of spatial frequencies. The modulation transfer function of the human visual system can be likened to a bandpass filter such that the attenuation of low frequencies results in edge enhancement and the higher-frequency limitation introduces a degree of smoothing. In the filter model proposed by Ginsburg,⁵ visual stimuli are decomposed into a hierarchy of filtered images from low to high bandpass, which together provide spatial information of form, detail and contrast.

The rationale of using a magnifying glass when examining images is well understood; this shifts the modulation sensitivity curve of the visual system in the spatial frequency domain by the amount of the magnification. The use of altered viewing distance or a minifying lens can also facilitate appreciation of relevant information by ensuring the best match in the spatial frequency domain between low contrast detail of a given size and the performance characteristics of the visual system. High-frequency noise present in the pixel margins can mask important information, and this can be attenuated by the technique of spatial filtration or by linear interpolation of the data on to a larger matrix.

During the past 10 years, several computational models of visual performance have been proposed depending essentially on a serial hierarchy of feature-based stages.⁶ Unfortunately, such models have not so far provided significant insight into human visual performance which has available more powerful parallel processing capabilities.

Many techniques for image processing and restoration are now available, and several of these are applied on a purely empirical basis. One cardinal principle which should be observed in applying any such technique is that it should provide better segmentation of the image consistent with the underlying anatomical, physiological or pathological substrate so that abnormalities can be better appreciated, as, for example, the subtraction technique which underlies the creation of phase contrast MRI angiograms. Adding color to MRI scans by equating shades of gray to spectral colours is, on the other hand, totally valueless because this would introduce artificial boundaries into the image which have no anatomical reality.

Modern imaging systems provide increasingly greater amounts of data which can be displayed in a wide variety of formats including 'pseudo-3D' projections and cine presenta-

tions, which allow currently under-utilized information channels in the observer to be used. The rapid cinematic presentation of contiguous transverse axial MRI body scans can allow information across several sections to be integrated more readily than on inspection of the individual hard copy images. In cine presentations, which are now a familiar mode of display in cardiac studies, image noise may be integrated by the observer, effectively increasing the signal-to-noise ratio and the perceptibility of relevant information.

5 COGNITIVE ASPECTS OF IMAGE INTERPRETATION

The principal cognitive factors which set a limit to an observer's capacity to apprehend the correct significance of information derived from an image set include our limited memory capacity, our selectivity in data abstraction, our inability to integrate a great deal of information simultaneously and that our simplification of judgment tasks introduces bias into our decision making.⁷ We know also of the human tendency to seek confirmatory rather than disconfirmatory evidence during problem solving.

To overcome the first two of these limitations the possibility of using computer-assisted diagnosis based on discriminant function analysis applied to specific radiological features has been suggested, for example, to assist in distinguishing multiple sclerosis from other diseases in MRI brain scans.⁸ If this method is to be used by several different radiologists, then it is necessary to ensure that an unambiguous and consistent method of codifying image descriptors is applied. This problem has recently been addressed in a study assessing high-signal foci on T_2 -weighted brain images.⁹ In this type of research a consensus agreement must be reached on image criteria in advance by participants so that inevitable interobserver variation is minimized.

6 ASSESSMENT OF THE DIAGNOSTIC EFFICACY OF IMAGE SETS

At the simplest level, asking observers to declare the relative fidelity with which some feature or features are displayed (e.g. on images derived from different MRI systems or produced with different pulse sequences) is open to several sources of bias which include a preference for the esthetically pleasing and inconsistencies between different observers in the use of any rating scale.

One method of reporting the diagnostic value of particular image sets is to assess the diagnostic accuracy or percentage of correct diagnoses achieved in a group of positive and negative cases for the particular pathology under consideration. This index has severe limitations, however, because it fails to take into account the prevalence of true-positive cases in the study population and also it does not reveal the balance of false-positive and false-negative errors and their clinical consequences. The latter deficiency is overcome by reporting the performance of an image set in terms of the sensitivity (or the fraction of patients having the pathology actually declared positive) and

the specificity (the fraction of patients without the disease declared negative).¹⁰

This is best achieved by determining all the different combinations of sensitivity and specificity that an imaging procedure provides in a particular detection task, for example the detection of focal liver lesions on MRI scans, as the observer's internal criterion for making the diagnosis is varied over all possible settings. The sensitivity (true-positive rate) is then plotted against $(1 - \text{specificity})$, the false-positive rate, to produce a receiver operating characteristic (ROC) curve.¹¹ In practice the observer is asked to select one of several levels of confidence [e.g. (1) definitely positive, (2) probably positive, (3) indeterminate, (4) probably negative, (5) definitely negative] or ratings to report their impression of whether an abnormality is present or not. The areas under the ROC curves of different observers for a given task provide an assessment of their inherent performance in carrying out the required discrimination. ROC analysis, although time-consuming, can be used to compare the detectability of specified abnormalities in image sets generated using different imaging systems or different protocols.

7 CONCLUSION

There are two principal ways in which diagnostic accuracy in the interpretation of MRI scans can be improved. Firstly, one can improve the quality of the image set which is generated so that relevant abnormalities are more readily appreciated. Secondly, one can address limitations of human observer performance and its inherent variability which has set us a new set of problems to solve in an era when the range of image formats and our ability to manipulate and transform them has never been greater.

Image Segmentation, Texture Analysis, Data Extraction, and Measurement

Stephen J. Riederer

Mayo Clinic, Rochester, MN, USA

1 INTRODUCTION

Very early in its development MRI was recognized as a modality in which the final image depended upon a variety of tissue-specific as well as operator-dependent parameters.¹ Considerable initial work was devoted to the determination of these dependences as well as the ‘optimization’ of scanning parameters for given tissue-specific quantities. However, several other questions were raised from a more fundamental standpoint.

One question was whether all relevant information for a section could be provided in an image of a fundamental parameter itself. An example would be the presentation of an image of the T_2 relaxation time for every pixel in the section of interest. This could possibly be used more effectively than the images actually acquired at one or more fixed echo times. We loosely call this the ‘simplification’ question.

A second broad, fundamental question was whether the specificity of MRI could be improved if tissues were somehow characterized by their multiple tissue-specific properties. For example, although actively malignant tissue and edema might both be distinguished from surrounding normal tissue because of a prolonged observed T_2 relaxation time, they are often not distinguished from each other on this basis alone. However, upon further consideration of other properties, such as the T_1 relaxation time, this could be possible. This use of multiple parameters—either independent measurements or derived parameters such as relaxation times—to attempt to distinguish various materials we loosely call the ‘characterization’ problem. When taken to an extreme one could even speculate that different types of cancer (e.g. different grades of malignancy) could be distinguished on the basis of where they lay in a plot of T_1 against T_2 space.

It is arguable to what degree these questions have been addressed in the decade since they were initially posed. With respect to the first of these, the ‘simplification’ question, very rarely are computed T_1 or T_2 images used in actual diagnosis made from MRI scans. Thus, one might conclude that the answer to this question is a resounding ‘No’. On the other hand, with many clinical MRI protocols, images are acquired at a ‘long’ repetition time (TR) of say, 2000 ms or more, at two different echo times, for example 30 and 80 ms. The long TR time effectively reduces or removes the dependence of the observed signal on the T_1 relaxation time. The radiologist may then attempt to detect relatively bright objects on the late echo

time (TE) image, indicative of a prolonged T_2 relaxation time, and then determine from the image acquired at the early echo time how the signal intensity of the object of interest compares with some standard, such as the cerebrospinal fluid (CSF) in known anatomic locations. In this way the radiologist is qualitatively performing an estimation of T_2 relaxation, or effectively placing the observed relaxation time of the object of interest into one of three coarse T_2 bins: (i) normal; (ii) modestly prolonged, indicative of many pathologies; or (iii) substantially prolonged, indicative of CSF or certain specific pathologies such as cavernous hemangioma in imaging of the liver.

Likewise, the degree of success with which the second question of ‘characterization’ has been addressed is also arguable. It is true that MRI cannot now be used noninvasively to determine the grade of malignancy or the primary site from which metastatic cancers originate. On the other hand, much of the art of clinical MRI interpretation involves the assessment of how the signal from a material behaves in one type versus another type of acquired image. For example a ‘ T_1 -weighted’ image, formed with a TR time comparable to the T_1 relaxation times of the materials under study and an echo time as short as possible, will often be acquired to get a good morphological picture and to assess any areas with abnormally long T_1 times. Additionally, ‘ T_2 -weighted’ images will generally also be acquired, and it is this combination of images which is initially considered in making any diagnosis. If necessary, additional sequences will be performed to improve specificity. For example, these might be sensitized to flow, chemical shift, or differences in susceptibility.

Since the time these two general questions were initially posed a decade ago, additional questions have been raised, in many cases much more specific. For example, is it possible automatically to determine the number and volume of multiple sclerosis lesions in the brain? If so, might it then be possible automatically to assess the effectiveness of any therapy by monitoring the total lesion volume over time? Similarly, is it possible automatically to monitor the volume of a primary brain tumor and determine the tumor location with respect to major blood vessels. Although in principle these processes can be done by the human observer, just as for the coarse binning of T_2 relaxation times for image interpretation, the complexity and volume of the data suggest that automation is the preferred approach.

The purpose of this article is to describe how data extracted from a set of magnetic resonance images acquired from some volume under study can be used to provide diagnostic information. This is a very broad area, ranging from straightforward image interpretation to elaborate, automated image segmentation techniques. In the next section an overview of data extraction techniques is provided, and then specific methods are discussed.

2 OVERVIEW OF DATA EXTRACTION METHODS

Image processing techniques such as image segmentation, texture analysis, and data extraction are most appropriately motivated by specific tasks or goals. The purpose of this section is to describe a hierarchy of such tasks or goals and show how a hierarchy of data extraction techniques follow. These goals and techniques are arranged in order, according to the relative

Table 1 Hierarchy of Data Extraction Techniques^a

Technique	Purpose	Input Images	Automated Processing	Example
<i>No additional processing</i>				
Image interpretation	Detection and characterization	T_1 -weighted, T_2 -weighted, and other (?) images	None, simple visual interpretation	Interpretation of 'standard' brain MRI scan
<i>Point Processing</i>				
Calculated relaxation times	Improved characterization	Set of T_1 or T_2 dependent images	Fitting procedure	Computation of T_2 times in basal ganglia ²
Calculation of other physical quantities	Quantification of physical phenomenon	Set of images acquired with different sensitivities to phenomenon	Fitting procedure coefficient	Estimation of diffusion ³
Synthetic images	Improved characterization and sensitivity	T_1 and T_2 dependent images	Fitting procedure and synthesis	Simulation of arbitrary pulse sequences ⁴⁻⁶
Generalized image combination	Improved conspicuity and sensitivity	Arbitrary set of images	Appropriate image combination	Eigenfiltering ⁷
<i>Regional processing</i>				
Image segmentation	Identification of specific structures	High contrast images of volume of interest	Seed planting; thresholding	Rendering of brain ⁸
Quantitative image processing	Volumetry; lesion counting	High contrast images of contiguous sections, multiple contrasts	Segmentation thresholding volume algorithm	Volume determination of hippocampus ⁹

^aThe simplest tasks (those requiring the least amount of automated image processing) are listed first. Tasks become more computationally intensive as one moves down the table.

amount of automated image processing required beyond standard image reconstruction. The least computationally intensive is presented first; the complexity of the data extraction technique increases subsequently. This hierarchy is shown in Table 1

The first task shown in Table 1 is one in which no additional automated processing is required. The data extraction technique is one of interpretation of MRI scans by the radiologist. The next tasks shown are ones involving 'point processing'. That is, pixel values from the same location from each of several images are used to determine some quantity, such as the estimate of a relaxation time. This is usually performed with some kind of automated technique, such as a regression. Also included in this general category are estimation of other physical parameters as well as methods for combining or synthesizing magnetic resonance images. The final entries to the table are those involving 'regional processing'. The mathematical algorithm used typically must consider groups of pixels in an image, such as by the use of thresholding or boundary detection. These algorithms are generally the most computationally intensive. Next, individual data extraction techniques are considered.

3 IMAGE INTERPRETATION

Image interpretation, defined as the radiological interpretation of the set of reconstructed images making up a clinical MRI examination, is presented as the lowest level data extraction technique. Despite this low level, this data extraction technique has proven to be the most useful by far during the 10 and more years in which MRI has been used clinically.

Clearly, an MRI examination can be indicated for many different reasons. However, a common purpose is the detection of any pathology, and, if any is detected, the characterization of the pathology. The data extraction method used by the radiologist, and that for which he or she has been trained, can be defined as magnetic resonance image interpretation.

Image interpretation is performed in many ways, and, indeed, can be regarded as a skill or art gained after many years of experience. As with any data extraction method, the success of the extraction is dictated to a great degree by the quality of the acquired images. The types of images acquired for an MRI examination depend significantly on the anatomy under study, the patient's clinical signs or symptoms, and the preferences of the radiologist. Thus, with the understanding

Figure 1 Schematic diagrams of the T_1 - and T_2 -weighted spin echo image signal as a function of the TR and TE times used in the pulse sequence. Normal tissue is designated by the broken curve, typical pathological tissue (with slightly increased T_1 and T_2 relaxation times relative to normal tissue) in bold. (a) For T_1 -weighted imaging the TR is chosen so that the difference in signal due to differential recovery is maximized. The echo time TE is chosen to be as short as possible. (b) For T_2 -weighted imaging the TR is chosen to be several T_1 time constants long (e.g. >2000 ms for many biological materials at typical field strengths for whole body MRI) in order to densitize the signal to T_1 differences between materials. The echo time TE is then chosen to provide high signal difference between materials on the basis of their T_2 relaxation times

that many protocols can be effective, the following suggested protocol is simply provided as a specific example. Once the patient has been properly positioned in the bore of the MRI scanner, typically some combination of ' T_1 -weighted' and ' T_2 -weighted' images are acquired of the volume under study. These are both commonly multislice rf refocused spin echo sequences. The TR times used cover a range, but typically one group of images is acquired using a TR time which is comparable to or less than the T_1 relaxation times of the materials in the volume. Such a TR provides signal differentiation on the basis of differences in T_1 , and such images are often called ' T_1 -weighted'. A specific TR/TE combination could be 500/15 ms. For the long TR set, images are commonly formed at two or more echo times, a late echo for ' T_2 '-weighting, and an early echo for 'pseudodensity' weighting. This combination of three images per section can be very effective in the detection and subsequent characterization of pathology. A specific example is $TR/TE_1/TE_2$ of 2500/30/100 ms.

These basic sequences are illustrated schematically in Figures 1(a) and (b). Figure 1(a) is a plot of the signal strength for two hypothetical materials as a function of the repetition (TR) and echo (TE) time used in the spin echo pulse sequence. The broken curve is designated as the signal for 'normal' tissue, with the solid curve corresponding to a material having slightly increased T_1 and T_2 relaxation times, common of many pathologies. For the T_1 -weighted sequence the TR is chosen to match approximately the T_1 times expected in the volume under study, causing separation of the relative signals. The echo time is chosen to be as short as possible to minimize any T_2 related effects.

Figure 1(b) shows a similar plot but for T_2 -weighted imaging. Here the TR time is chosen to be several T_1 time constants long so that the magnetization of most materials has substantially recovered to equilibrium. Next, several echo times might be used for the acquisition of data, the latter echo being

that which provides large separation between signals as based on T_2 differences. Although these sequences have been available for 10 years, even today they remain the workhorses of clinical MRI.

One may question why simple image interpretation is the most effective data extraction technique used today, and yet the one which requires virtually no image processing after the reconstruction operation. In the author's opinion this is due to several things. First, the degree of data extraction required for routine image interpretation in MRI does not require computation. The radiologist can estimate relative degrees of relaxation by comparing signals from questionable materials with those of standards in the same image, such as CSF or fat. Second, the quality of contemporary magnetic resonance images is so high that except for very specific applications little additional sensitivity is to be gained from more elaborate means beyond image interpretation. Third, there is considerable overlap in relaxation times and densities of normal, neoplastic, ischemic, inflammatory, and malignant tissues, thereby suggesting that the extra effort spent in performing data extraction procedures may not in the long run be worth the effort in improving characterization or specificity. These first three reasons are fundamental. Finally, from a more practical standpoint, clinical reality requires that image interpretation be performed shortly after the MRI examination has been completed. There is no time for time consuming image processing algorithms. Nonetheless, despite the success of image interpretation as the most useful means for routinely extracting data from magnetic resonance images, the further development of data extraction methods is a worthwhile undertaking.

4 CALCULATED RELAXATION TIMES AND OTHER PHYSICAL PARAMETERS

Relaxation times are fundamental tissue-specific quantities in magnetic resonance. They characterize the state of the tissue under study. An early hypothesis in the developmental stages of MRI was that relaxation times could be used to characterize disease. Elevation of T_1 relaxation time was noted early by Damadian,¹⁰ while Herfkens et al.¹¹ undertook a study in which both T_1 and T_2 relaxation times were measured from normal tissues and tumors in mice. Although normal tissues could be distinguished to some extent on the two-dimensional plot, the points corresponding to tumor covered a broad range. This was very foreboding as it suggested that malignant tissue could not be well characterized by the use of relaxation times, and this has proven to be the case.

Additional articles in the Encyclopedia cover the estimation of and use of relaxation times (see *Relaxation Measurements in Imaging Studies*, *Relaxation Measurements in Whole Body MRI: Clinical Utility*, and *Relaxometry of Tissue*). Although relaxation times are not routinely calculated as part of the every day MRI examination of a patient, estimation of relaxation time is very important in other ways.

In Section 3 the emphasis was on the success with which directly acquired magnetic resonance images can be interpreted. This success is largely because the images themselves are acquired at TR and TE times which are optimally 'tuned' to the relaxation times of the materials under study. Without knowledge of such relaxation times it would be difficult to tune the

Table 2 Summary of Estimated T_1 Relaxation Times in Humans in Liver and Spleen (Milliseconds at 1.5 T)

Volunteer	Liver T_1	Spleen T_1
1	329	797
2	364	866
3	398	745
4	398	866
5	415	848
6	415	779
7	415	797
8	433	918
9	450	832
10	468	814
11	468	883
12	468	883
13	485	883
14	589	900
Mean $\pm$ SD	435 $\pm$ 62	844 $\pm$ 51

sequences. The following example may show how mean relaxation times can be used for such sequence ‘tuning’ as well as illustrate the significant interindividual variability in relaxation times.

Consider the specific task of selecting the proper inversion time (TI) of an inversion recovery pulse sequence which is to be used to detect pathology in the liver. Such pathology is often metastatic cancer, the relaxation times of which are known to mimic those of normal spleen.¹² This task was addressed by first measuring the T_1 relaxation times for both liver and spleen in a set of 14 volunteers. In this case the T_1 was estimated by using a breath-hold magnetization prepared pulse sequence¹³ in which the TI was varied from one image to the next until the signal from the targeted organ was nulled out as well as possible. The T_1 was then estimated as $TI/\ln(2)$, where TI' was that inversion time providing the best nulling. The results are shown in Table 2.

The mean T_1 values, 435 and 844 ms for liver and spleen, respectively, were subsequently used in the selection of a TI of 550 ms as being a reliable value and nearly optimum for the ranges of T_1 values encountered. This value has been used effectively in many subsequent clinical studies. This example shows the importance of determining relaxation times and using these values in tuning a pulse sequence. Another incidental point to note in this study is the extent of the variation of T_1 values encountered. The standard deviation of liver T_1 exceeded 10% of the mean value, while that for spleen exceeded 5%. With variations this large in the patient population alone, it is easy to see why the use of absolute relaxation times can have considerable intrinsic imprecision.

The relative lack of specificity of relaxation time analysis has tempered enthusiasm about this technique. Another plausible limiting factor is the potentially long acquisition time required to obtain an adequate set of images to be input to the fitting algorithm used for the relaxation estimation. This can be especially problematic in imaging of the body, where respiratory motion induced artifacts can degrade image quality if the acquisition time is longer than a breath-hold. However, recent developments in fast scan techniques may facilitate the deter-

mination of relaxation times for abdominal and cardiac structures. An example of this is shown in Figure 2, which is a comparison of images all acquired of the same section of the abdomen. Note the large lesion positioned anteriorly [arrowed in Figure 2(a)]. Figures 2(a) and (b) were acquired using standard, several minute long, rf-refocused spin echo techniques: Figure 2(a) TR/TE 250/14 ms, 134 s acquisition time; Figure 2(b) TR/TE 2500/60 ms, 1015 s acquisition time. Figures 2(c) and (d) were both acquired with breath-hold acquisition techniques, magnetization-prepared gradient echo¹³ and interleaved echo planar techniques¹⁴ respectively: Figure 2(c) $TI/TR/TE$ 550/9/4.5 ms, 8 s acquisition time; Figure 2(d) TR/TE 2000/66 ms, 18 s acquisition time. Note the visually comparable liver lesion contrast-to-noise ratio (CNR) in Figure 2(c) versus Figure 2(a) and in Figure 2(d) versus Figure 2(b). Conceivably the sequences used in Figures 2(c) and (d) could be modified to provide images at alternative TI and TE times, respectively, so as to provide suitable data for the estimation of T_1 and T_2 relaxation times uncorrupted by motion artifacts.

A specific example of the use of relaxation times in the explanation of an observed phenomenon in magnetic resonance images is the work of Darwin et al.,² in which the T_2 relaxation time of structures in the basal ganglia correlated with the distribution of iron in the normal brain. This is due to the gradual accumulation of ferritin in these structures with age.

The use of several measurements at a specific location to estimate the value of a physical parameter at that location needs not be limited to relaxation times. Other techniques which can technically be considered ‘data extraction’ methods include the estimation of diffusion coefficients,^{3,15} or of inhomogeneity-induced signal decay, sometimes referred to as T_2^* , or maps of exchange coefficients related to magnetization transfer.¹⁶ In all cases several images with different relative sensitivities to the phenomenon under study are acquired, and the relationship between observed signal intensity and the phenomenon is inverted to enable determination of an actual numerical value for the relevant quantity.

5 SYNTHETIC IMAGES AND IMAGE COMBINATION

The next entries in Table 1 also correspond to point processing. The first, image synthesis,⁴⁻⁶ can be regarded as an extension of the computation of relaxation times. The concept of synthetic imaging is first to acquire images for several sets of pulse sequence parameters and then mathematically to simulate or ‘synthesize’ images at alternative parameter values. This process was motivated by the hypothesis that sensitivity or specificity could be improved if one could observe images of an anatomic section at TR and TE times different from those used in the actual acquisition. In fact, the synthesis step can be performed in ‘real time’; i.e. the observer can interactively adjust a sequence parameter such as TE and immediately see the effect on the image.

Once the original images are acquired, an intermediate step is generally one in which images of the relaxation times are formed for each section of interest. That is, T_1 , T_2 , and M_0 are determined for each pixel in the image. In the final step of synthesis these relaxation time images are mathematically

Figure 2 Comparison of conventional non-breath-hold (a) T_1 and (b) T_2 weighted images of the liver with (c) breath-hold T_1 and (d) T_2 -weighted images of the same anatomic section. A large lesion is seen [arrowed in (a)] in all four images. The overall quality of the breath-hold images approximately matches that of the non-breath-hold results

combined. For example, if the signal S of a spin echo pulse sequence were to be synthesized at sequence parameters TR and TE , the density and relaxation time images would be combined mathematically:

$$S(x, y) = M_0(x, y) \{1 - \exp[-TR/T_1(x, y)]\} \exp[-TE/T_2(x, y)] \quad (1)$$

where the fact that S , M_0 , T_1 , and T_2 are images is explicitly noted by the (x, y) dependence. At this point it should be clear that the equation used for the synthesis need not correspond to the signal behavior for the pulse sequence used in the acquisition. That is, the original images could have been acquired with a spin echo pulse sequence but used to synthesize inver-

sion-recovery images. In fact, such an example is shown in Figure 3 which shows a comparison of a synthetic inversion-recovery image (right) generated from images acquired using a standard spin echo pulse sequence. Also shown is an inversion-recovery image acquired directly (left) using the same parameters as those used for the synthesis. Note the close visual correspondence.

Image synthesis is limited by several factors. First, the signal-to-noise ratio (S/N) in the original images ultimately limits the S/N which can be attained in the synthesis step.^{17,18} For example, it is not possible without significant S/N penalty to acquire images at, say, TR values of 100 and 200 ms and then synthesize at TR 2500 ms. Second, the process is also poten-

Figure 3 Comparison of synthetic inversion-recovery image (right) formed from spin echo images and a directly acquired inversion-recovery image (left)

tially limited in the accuracy with which it can portray the actual performance of pulse sequences. Effects of B_1 inhomogeneity, flow or motion, misregistration of the acquired images, or a breakdown of the monoexponential behavior of relaxation can all cause inaccuracies. Finally, for routine interpretation of MRI examinations the added diagnostic capability provided by image synthesis has not proven to be significant. That is, the acquired images themselves often provide adequate sensitivity and specificity.

Despite these limitations, when used in a real time or interactive mode, image synthesis can be an effective teaching tool which illustrates visually and rapidly the effect of different pulse sequence parameters on the appearance of MR images.

It was noted in the above discussion that the signal which is synthesized need not correspond to the pulse sequence used for the actual acquisition of the original images. In fact, this concept can be further generalized in that the mathematical combination used need not correspond to any pulse sequence. From an electrical engineering standpoint one has a set of measurements $\{S_i\}$, and from these one wishes to combine them in some optimum fashion according to a relevant criterion. For example, one such criterion is to form that image combination which provides the highest net CNR between two targeted structures. For the case in which the measurements are to be linearly combined, the i th image weighted by the coefficient k_i , it is straightforward to show that the optimum k_i value is proportional to the CNR in the i th image. This is sometimes referred to as a 'matched filter'. If one knew beforehand the two targeted structures to be distinguished, then rather than acquire a set of images each with a different pulse sequence, a superior procedure would be to spend all of the allotted acquisition time in performing that single pulse sequence which provided the highest CNR, performing signal averaging if time allowed.

Image combination methods can potentially be useful for cases in which the criterion to be considered in the optimiz-

ation is more involved than CNR maximization alone. For example, one may wish to optimize the contrast between materials A and B, subject to minimizing the contrast between materials A and C. This problem has been approached in several ways, but an elegant theory for addressing this uses 'eigenimages'.⁷ In the same way that diagonalization of a matrix problem can be performed using eigenvectors in linear algebra, a set of coefficients $\{k_i\}$ can be derived from the observed signal intensities which performs the desired task.

Although the theory of linear image combination is well-posed, and the results are straightforward to implement, in practice, linear image combination has not proven to be a widely accepted method in clinical MRI. The reasons are much the same as those for the relative lack of use of relaxation times and of synthetic images. The original acquired images often have excellent sensitivity to pathology in the first place. If the radiologist detects pathology but cannot characterize it using the images already in hand, then it is straightforward to order another pulse sequence which addresses a specific differential question. This process thus circumvents the image combination route. Another advantage is that, unlike image combination, this approach has no requirement that the images from all sequences be spatially registered to a very high degree of accuracy.

6 IMAGE SEGMENTATION

The last entries in the hierarchy of Table 1 pertain to processes which are more ambitious in terms of what the processing is to provide. A general goal of these techniques is the automated determination of some structure of interest. This process of decomposing an image set consisting of hundreds of thousands of voxels into a much smaller number of identifiable structures can be called 'image segmentation'.

The technique of image segmentation is not limited to the practice of MRI. In fact, a good reference on basic techniques for image segmentation is found in the work by Udupa and Herman.¹⁹ Once structures in an image are segmented, additional processes can be performed such as integration or rendering.⁸ Segmentation techniques can be broadly categorized as those based on the determination of boundaries or those based on the identification of specific regions.

Boundary-based algorithms are those which perform mathematical tests on the reconstructed pixel values in an image, which are designed to be sensitive to large changes in value in adjoining or nearly adjoining pixels. Typically a gradient operator is used. If the calculated gradient between two pixels is adequately large, then an 'edge' is designated as occurring between the two pixels. Next, the neighboring pixels are considered and the gradient operator is again applied in various directions. In this way the edge or boundary between the materials can be tracked across the image. For small objects this process will generally result in the boundary eventually finding its way back to its origin, resulting in a closed curve and a segmented object. For the typical case in which a set of images is acquired corresponding to parallel sections, the process is repeated for each image for that region containing the structure to be segmented. In this way an object which extends across several sections can be segmented in its entirety.

Clearly, an alternative to automated boundary detection algorithms is manual tracing. With this approach the operator traces with a cursor the suspected edge between various materials until the structure of interest is circumscribed. Just as for the automated case described above, this can be repeated if necessary for multiple images which span the volume containing the structure.

Region identification algorithms make use of the reconstructed signal intensities within the image. One approach is to use thresholding of the signal as a means for segmenting a specific structure. That is, those pixels whose reconstructed signal values fall between S_1 and S_2 are assumed to consist of material X, etc.

Simple thresholding can have limited success in MRI because many materials can have an overlap in their magnetic resonance signal, such distinctions being further compromised by inadequate S/N in the images. One way to address this is to apply the equivalent of thresholding to more than one image of the same anatomic section. If the reconstructed signal falls between S_1 and S_2 in image I_1 , and between S_3 and S_4 in image I_2 , then such pixels are assumed to consist of material X. This process is shown schematically in Figure 4. One axis corresponds to the reconstructed signal value in one specific image, for example the early echo in a dual-echo sequence at a long TR time. The second axis corresponds to the signal in the late echo. Each pixel in the image is mapped to a specific point in this feature plot, the coordinates of that point determined by the signals in the early and late echo images for that pixel. Clusters of points in such feature space plots are assumed to correspond to specific tissue types, such as gray matter or white matter in brain imaging. Such techniques have been used with some success in designating structures in magnetic resonance images of the brain and body.²⁰

Clearly, the success of segmentation depends critically on the quality of the acquired images. Ideally the acquisition parameters are chosen with the type of segmentation already in

Figure 4 Schematic diagram of feature space analysis. Each pixel in an anatomic section of interest is assigned a point in this space on the basis of the signal at that pixel in two images. In principle, segmentation can be performed on the basis of clustering in such a feature space plot of pixels of similar make-up. In this example, three different materials are suggested

mind. For example, if liver cancer is to be segmented from normal liver parenchyma in inversion-recovery images, then the same considerations discussed in Section 4 with respect to contrast optimization would also be relevant here. In fact, inversion-recovery or other heavily T_1 -weighted sequences can be effective in providing large contrasts between different materials.

An example of the application of segmentation techniques in MRI is the work by Jack et al.⁹ in which the side of origin, right or left, of temporal lobe seizure patients was studied by volume measurements of the hippocampal formation. Oblique coronal contiguous 4 mm-thick T_1 -weighted images were acquired of the brain. An image oriented similarly to those used in the study is shown in Figure 5. The hippocampal formation was manually segmented from the images and the volumes determined. Compared with other MRI-based tests, such as increased signal intensity on the suspect side in T_2 -weighted images, the volumetric approach had significantly increased usefulness.

7 SUMMARY

Data extraction encompasses a broad range of techniques in MRI. An excellent, relatively recent review of data extraction

Figure 5 Example of identification of the right hippocampal structure (arrow) in an oblique coronal section of the brain of a normal subject. In this example the segmentation was performed by manual tracing. Such segmented regions can be pooled from contiguous sections and integrated to form an estimate of the hippocampal volume

methods in MRI is the book edited by Higer and Bielke.²⁰ Data extraction techniques also vary in their computational complexity. The least computationally intensive method of data extraction is also that which has been proven to be most useful in clinical MRI, namely radiological image interpretation. Techniques such as the determination of relaxation times have not in general added significantly to sensitivity or specificity in everyday MRI, but such methods are absolutely essential in assisting in establishing proper pulse sequence parameters. The use of automated methods is expected to grow in specific instances in which the complexity of the processing, the volume of data to be considered, and the sensitivity of the test preclude simple human interpretation. Examples include the volumetric measurements and the automated determination of the lesion load, such as in multiple sclerosis. Further improvements in the quality of the acquired images themselves, such as improved S/N due to topical coil arrays or reduced artifacts resulting from breath-hold acquisition times, will also enable improved performance of automated data extraction techniques.

Stephen J. Riederer. b 1951. B.A., University of Wisconsin. S.M., Massachusetts Institute of Technology; Ph.D., University of Wisconsin. Actively performing research in technical aspects of diagnostic medical imaging 1974-present. Introduced to NMR in 1983. Approx. 100 journal articles. Principal interests are fast scan techniques in MRI, abdominal imaging, high speed cardiovascular imaging, and real time interactive MRI techniques including MR fluoroscopy.

Outcome and Efficacy— Analysis of Healthcare Models

Martin J. Lipton, Charles E. Metz, and Larry A. Ranahan

The University of Chicago, IL, USA

1 INTRODUCTION

Public and private attention in the USA has focused sharply on health care reform during the early 1990s. Health care costs seem to be out of control, and enormous pressure to reduce these costs has emerged. Health care is a colossal business—perhaps the world's largest. Most wealthy nations spend a substantial percentage of their gross domestic product (GDP) on health care, with the USA heading the pack (Figure 1) and with the UK's National Health Service (NHS) once boasting that it took over from the Red Army as Europe's biggest employer.¹ However, people working in health care often deny that they are in 'business' at all. Many physicians believe that their long, demanding training places them at the head of the professions, not down among service providers. Moreover, physicians often resent attempts to constrain their professional activities and demands for objective evidence concerning the outcomes of those activities. This attitude is now being challenged, but it remains widespread.

Government intervention in medicine has a long history, perhaps because people often have doubted that public-market forces can stimulate and control health care like other goods and services. Hammurabi, King of Babylon, enacted laws in 2200 BC that limited doctor's fees and provided punishments for those who injured their patients. Mandarins in ancient China paid doctors only if their patients became well.¹ Hence, it is clear that many current trends in health care—capitation payments, prospective budgets, and health maintenance organizations (HMOs), etc.—are not new concepts. Today, the financing and delivery of health care differ greatly in different countries, but the financial crises and turmoil associated with health care in these countries are strikingly similar. A common theme emerges: the need for governments to ensure universal access to health care at reasonable cost, particularly as populations age, and the need to limit the utilization of increasingly sophisticated (and expensive) technology. However, most governments appear to be dealing with health-care reform in isolation. Few nations have tried to understand and learn from the mistakes of others, perhaps in part because none has found a satisfactory solution, and perhaps in part because each country believes that at least some aspects of its own system are inherently best.

All systems of health care are imperfect and expensive. Governments have jumped into the marketplace in two princi-

Figure 1 Health care spending per person in various countries as a percentage of GDP, by year. (Reproduced by permission of the Economist Newspaper Group, Inc., © 1991, from J. Peet, *The Economist*, 6 July 1991 (Insert), 320, 1)

pal ways. One involves regulating both insurers and doctors. This regulation may be broad, or it may narrowly control prices, volumes and even methods of treatment. The alternative is subsidy of health care costs.

Health care systems can be classified according to three general models, though most nations' systems include aspects of more than one:

1. The US model is based upon private health insurance, which usually is purchased by individuals or families through their employer. Health care is delivered largely by private hospitals and physicians.
2. In the Beveridge model, named after the founder of the UK's NHS, health care is funded by government and paid from general taxes. Care is delivered by publicly owned hospitals and salaried physicians. Sweden and Italy have similar systems.
3. The Bismarck system, named after the founder of Germany's compulsory social insurance, represents a mixed form in which health care is publicly financed, usually by payroll taxes, but is provided primarily by private physicians and hospitals. Japan, Canada, Holland, and France employ variations of this hybrid model.

Figure 2 shows annual percentage increases in health care spending per person by decade for the past 30 years. The continuing rise in the costs of the Canadian and American system is evident. Employers who bear the cost of health insurance in the USA are struggling to pay the escalating premiums, which are being driven more and more aggressively by for-profit insurers. Many large employers are underwriting the medical bills of their employees directly, in order to escape state regulation. This 'self-insurance', usually through an intermediary, is now allowed by Federal law. Medicare, the government insurer in the USA, spends more than US \$110 billion annually, which is roughly twice the cost of the UK's NHS.¹ Fee-for-service payments, which can influence patient management and therefore costs, are seen by many as a key aspect of the US health-care system's current difficulties.

Figure 2 Annual percentage increases in real (based on GDP deflators) health care spending per person in various countries, by decade. (Reproduced by permission of the Economist Newspaper Group, Inc., J. Peet, *The Economist*, 6 July 1991 (Insert), 320, 1)

Increasing health care costs have led, naturally enough, to increasing demands from insurers for objective, quantitative evidence concerning the effectiveness of diagnostic and therapeutic techniques. However, health care evaluation of this kind is difficult, in part due to the complexity of the technical and ethical issues that are involved, but perhaps also in part because physicians and hospitals traditionally have managed patients with little regard or knowledge of costs or outcomes. Little information is available concerning real costs—which may be quite different from what doctors charge. Systematic accounting of outcomes is also rare, though Florence Nightingale called for detailed records of what happens to patients and why more than a century ago:¹ there is little concrete evidence regarding which procedures work and for which patients. Such information is becoming crucial in the new climate of managed care.

2 LEVELS AT WHICH EFFICACY AND EFFECTIVENESS CAN BE ADDRESSED

A diagnostic test has value—and therefore is justifiable—only if it is effective in some sense. Strictly, ‘efficacy’ indicates the value of a test when it is performed and utilized under ideal conditions, whereas ‘effectiveness’ indicates the test’s value under typical or routine conditions. The distinction between these terms is not one of mere technical jargon; *Webster’s New Collegiate Dictionary*,² for example, defines ‘effective’ as ‘producing a decided, decisive, or desired result’ but ‘efficacy’ as ‘the power to produce an effect’ (emphasis added). Many of the same issues arise in considerations of both efficacy and effectiveness, however, so in the following we use ‘efficacy’ broadly to indicate both, emphasizing the distinction only where necessary.

‘Value’ can be conceived and defined in many ways, of course, so every meaningful analysis of diagnostic efficacy must include a clear indication of the sense in which value is to be measured. A conceptually useful model that unites the various ways in which efficacy can be defined and measured was formulated in the early 1980s by Scientific Committee No. 69 of the National Council on Radiation Protection and Measurements.³ This model considers the efficacy of a diagnostic test in terms of hierarchical levels that range from the test’s technical behavior to its overall impact on society. An

important attribute of the model is that efficacy at lower levels is necessary, but not sufficient, for efficacy at higher levels. Efficacy at the model’s higher levels usually is of greater direct interest, but lower level efficacy is almost always easier to measure reliably. Fortunately, efficacy at the higher levels sometimes can be estimated from measurements at lower levels by use of collateral data and (hopefully) appropriate assumptions.

The model’s six tiers are:

1. *Technical efficacy.* At this lowest level, a diagnostic test is considered efficacious if its result is accurate and precise in a physical sense—for example, if the test measures the physical attribute that it purports to measure and if its results are reproducible. Aspects of technical efficacy in medical imaging include spatial and/or temporal resolution, noise magnitude and texture, and contrast sensitivity. Standard protocols for the measurement of technical efficacy have been formulated in radiography,^{4–7} for example. Protocols for such measurements are less well established in MRI, in part due to the very broad range of conditions under which images can be acquired in that modality, but some guidelines are available.⁸
2. *Diagnostic-accuracy efficacy.* This level concerns the extent to which the results of a diagnostic test agree, in some statistical sense, with patients’ actual states of health or disease. Virtually all practical measures of diagnostic-accuracy efficacy that have been proposed to date quantify the ability of a test to distinguish between two (usually composite) states of truth, such as ‘normal’ versus ‘abnormal’, or ‘positive’ versus ‘negative’ with respect to a specified disease. Examples of diagnostic-accuracy measures include per cent correct, sensitivity and specificity, and receiver operating characteristic (ROC) curves. Of these, an ROC curve is the most comprehensive in that it displays all the combinations of sensitivity and specificity which a diagnostic test is able to provide as the test’s ‘decision criterion’ is varied. The advantages of ROC analysis over more traditional measures of diagnostic accuracy have been discussed by Metz.^{9,10}
3. *Diagnostic-thinking efficacy.* If a diagnostic test’s sensitivity and specificity (level 2 efficacy) are known, one can compute the factor by which the objective odds of disease change after the test is performed, but the question of whether the test affects physicians’ subjective estimates of disease likelihood must be answered empirically.³ This intermediate level of efficacy is difficult to quantify, but it provides an important conceptual link between the more clearly specified levels above and below.¹¹ Measurement of diagnostic-thinking efficacy is complicated by the difficulty of interpreting subjective probability estimates,¹² but appropriately designed studies can identify situations in which the impact of a test on diagnostic thinking is clearly great or small. Large-scale studies of diagnostic-thinking efficacy have been reported by Lusted et al.¹³ and by the US Food and Drug Administration,¹⁴ for example.
4. *Therapeutic efficacy.* This is the lowest level at which the effects of a diagnostic test on patient management are assessed directly. The basic question here is how and by how much a particular diagnostic test changes the way in which a patient is treated—i.e. how does therapy differ when it is chosen with and without the diagnostic test? It is

important to notice that carefully controlled studies of a diagnostic test at this level require either that patients' therapy be thoroughly planned without the test's result and then replanned after the test's result is provided, or that a randomly selected control group of patients be treated without all the diagnostic information that might otherwise be obtained. Despite the difficulties raised by these practical and ethical issues, therapeutic efficacy has been studied in preoperative chest radiography of children^{15,16} and in computed body tomography,^{17,18} for example.

5. *Patient-outcome efficacy.* Here the goal of diagnostic medicine is confronted directly: a diagnostic test is considered efficacious (or effective) at this level only if patient health (as measured in 'quality-adjusted life years', for example) is demonstrably improved by use of the test. This is the kind of efficacy which is of greatest interest to most patients and physicians, and it is an indispensable component of any meaningful cost-benefit or cost-effectiveness analysis. However, definitive assessments of patient-outcome efficacy require prospective randomized and controlled clinical trials in which practical, statistical, and ethical problems can be formidable.³ Therefore, patient-outcome efficacy often is inferred by using decision analysis to combine measurements of diagnostic accuracy (i.e. level-2 efficacy) with epidemiological and other collateral data. Relationships between ROC analysis, in particular, and cost-benefit or cost-effectiveness analysis have been described by Metz and co-workers,^{9,19} Phelps and Mushlin,²⁰ and Sainfort.²¹
6. *Societal efficacy.* Any cost-benefit or cost-effectiveness analysis of a diagnostic test at the patient-outcome level focuses on the benefits and effectiveness that accrue to the patients who are candidates for the test. However, one must ask 'Cost to whom?'. The inescapable answer that medical costs are borne increasingly by society as a whole implies that social utilities should somehow be taken into account when benefits and effectiveness are evaluated. This is the domain of 'societal efficacy', which in principle merges technical, economic, and political considerations to assess diagnostic tests within the context of the social endeavor. Consideration of societal efficacy leads inevitably to philosophical and political questions of how society's resources should be allocated—not only within a 'health care budget' but also more broadly. Rigorously scientific measurements and wholly rational analyses of efficacy at this level are impossible, of course, but 'the challenge is to bring policy and practice into line with knowledge'²² and to increase knowledge that will inform policy and practice.

Studies that attempt to assess diagnostic tests must differ in many ways across the six levels of efficacy, but several practical issues arise in virtually all efficacy studies. Perhaps the most fundamental issue is the need to avoid effects of sampling bias, which may arise in a variety of subtle ways and can lead to misleading estimates or conclusions.^{23,24} Another common issue is the decision as to whether the efficacy of each diagnostic test of interest must be quantified in strictly defined units on some meaningful scale or, alternatively, needs only to be ranked relative to other tests. Absolute measurements of efficacy are desirable in principle, but appropriately designed 'ranking' studies often are more practical because their results may be much less sensitive to sampling bias.²⁵ Similarly, the relative merits of prospective and retrospective studies should

be considered carefully in each situation; carefully controlled prospective studies are preferable in principle, but appropriately designed retrospective studies are often more practical. Yet another issue in most efficacy studies is the question of whether a diagnostic test should be assessed in isolation or in the context of its use within a particular diagnostic strategy. Trade-offs between rigor and practicality are inevitable in any assessment of efficacy; the key needs are to consider those trade-offs rationally and to report them clearly.

3 LEVELS AT WHICH COSTS CAN BE ADDRESSED

Government and industry are demanding objective evidence and criteria upon which to make health care purchasing decisions. This information will be based upon the aggregate outcomes of health system activity.²⁶⁻³⁰ An important driving force behind efficacy and effectiveness research is cost or, more broadly, health care economics. Most recent cost-containment efforts in the USA have focused on the reduction of administrative and production costs, as is evident from numerous media announcements of corporate and hospital mergers, consolidations, restructurings, reductions in staff, and hard bargaining with labor unions and producers of equipment and supplies. Outcomes analysis shifts the focus of cost containment from the cost of each unit of production, or episode of care, to maintaining the health of each patient from cradle to grave. The demand for cost-effective health care ultimately will require difficult choices concerning the allocation of financial resources. To the greatest degree possible, such decisions should be based upon comprehensive, scientifically derived knowledge of the efficacy and effectiveness of competing diagnostic and therapeutic methods and technologies.

US industry views employee health care as a commodity—a component of the cost of production—and health care providers as suppliers. Quality control is taken for granted in business, and perhaps is illustrated best by the Japanese concept of *kaizen*—the philosophy of overall system improvement.³¹ Therefore, health care quality must be defined, measured and controlled, and the costs of these services must be reduced and guaranteed prospectively. Outcome analysis has become important because it measures that which is being supplied. Quality assessment and outcome analysis are not new, of course, but until now they have been applied rarely to medicine, which traditionally has been seen as a 'noble' profession in which performance could not—or should not—be measured. Outcome analysis is here to stay, however, and it requires that the performance of radiologists, as well as other physicians, be evaluated as part of the overall health care system.

Outcome analysis is motivated in large part today by the need to determine cost effectiveness, in which competing technologies are compared in terms of their costs and results. This process requires both the identification of costs and the measurement of benefits derived.³² The cost of any technology can be measured in terms of three components: direct, indirect, and intangible. Direct costs include capital and operating expenses for acquisition, personnel, materials and supplies, maintenance and support, etc. Indirect costs include elements such as administration, overheads, utilities, support personnel, and others. Intangible costs are far more complex and often

Figure 3 The dimensions of economic analyses. (Reproduced with permission from C. Bombardier and J. Eisenberg, *J. Rheumatol.*, 1985, 12, 201)

become the critical issue in outcome analysis. These latter costs can be represented by a trade-off in investments in competing technologies, as measured at the highest levels in the six-tier model.

In any cost-benefit analysis, perspective, or point of view, is the third dimension of the process. These perspectives include those of the provider, payer, patient, and society.³³ Each point of view must be considered in order to establish a complete understanding of the economic decision that is required in determining the most efficacious technologies. MRI technology is particularly vulnerable due to its high acquisition and support costs, and often competes against lower cost technologies. It is critically important for future outcome analysis research to focus on these factors in order to provide an objective basis for decisions concerning the appropriate use of medical technology.

In economic terms, the three-dimensional model of types of analysis, types of costs and benefits, and point of view (Figure 3) takes on additional meanings. Direct costs include nonmedical costs related to a specific illness that are often borne by the patient, such as transportation or lost income, which can be measured in objective terms. Measurements of indirect costs must attempt to include the cost due to a loss of livelihood or life. These can be quantified in terms of a human capital approach,³⁴ loss of earning potential for individuals, or lost productivity for employers. Intangible costs are frequently framed in terms of pain and suffering, which are beginning to be assessed in terms of quality-adjusted life years (QALYs). This outcome-based analytical framework is intended to pro-

vide a rational foundation for decisions concerning resource allocation.

4 OUTCOMES AND EFFICACY RESEARCH IN RADIOLOGY

Traditionally, the outcome of diagnostic radiology is thought of as images—usually recorded on X-ray film—and typed reports of their interpretation. However, individual reports are no more than isolated pieces of data, and the task of integrating these data into a diagnosis often is left to the referring clinician. As Drucker has pointed out, data become useful information only when they are endowed with relevance and purpose.³⁵ Radiologists are in an especially good position to access, collate, and distribute this information, because their practice now includes an increasing variety of sophisticated computerized methods for displaying, managing, transferring, and interpreting image data. In particular, radiologists currently enjoy a unique opportunity to study the value of the vast array of new imaging technology in the context of specific diagnostic tasks and patient populations. MRI, the most recently developed medical imaging technology, is especially well suited to this task. Moreover, objective demonstration of the benefits of MRI is crucial, because high-technology imaging costs in medicine are widely blamed for the current rise in health care costs, despite the fact that only 3.5% of expenditures for health care is spent on radiology.³⁶ However, a variety of difficulties must be faced in attempting to assess the extent to which a diagnostic study influences patient outcomes. A survey of the literature since 1985, soon after MRI was introduced, illustrates many of the fundamental problems of outcomes research in radiology. These problems are sketched briefly here, with examples.

In their day-to-day work, referring physicians and radiologists usually are unable to take into account objective information concerning patient-outcome (level 5) efficacy. Most referring physicians and radiologists are interested in and sensitive to their patient's outcomes, but objective and systematically collected level-5 information usually is either unavailable—because the necessary large randomized controlled trials have not been performed—or unknown—because a trial's results were published in an obscure journal or described in abstruse methodological jargon. Some radiological procedures, notably mammography for diagnosis of breast cancer, have been studied at level 5. However, virtually all assessment studies of MRI have been restricted to levels 1–3.

A physician may order a diagnostic imaging examination for many reasons: to make a diagnosis; to guide therapy; to assess prognosis; to avoid successful malpractice litigation; to increase income; to accede to the referring physician or patient's demands in the case of the radiologist; or to reassure the patient (and/or the physician). Ultimately, however, the efficacy of diagnostic imaging must be viewed as one part of the entire process of medical care, which exists to improve patients' well-being. This end-point lies in the domain of level-5 efficacy, as described above.

An awareness of potential sources of bias in evaluation studies is basic to any understanding of outcome efficacy. For example, a new imaging technology such as MRI evolves through several phases. The first is a discovery phase that

involves using the modality in patients to determine if disease, often severe, can be distinguished from healthy, normal volunteers.³⁷ This has been the foundation of early clinical trials since the discovery of X-rays by Roentgen in 1895, and it provides a basis for estimating rates of false-positive results. However, diagnostic accuracy (i.e. level-2 efficacy or effectiveness) often is found to fall as the technology is applied to a broader spectrum of patients.²³ This has been called the 'diffusion' phase. Moreover, many—often the vast majority of—evaluation studies are performed in tertiary academic centers, where referral bias is inherent.

Ideally, each diagnostic technique would be evaluated in each diagnostic setting by means of a large-scale, carefully controlled study that is designed and carried out by investigators who are expert in evaluation methodology. In practice, however, assessments of efficacy are often based upon published research that varies greatly in rigor and quality. For example, Cooper and colleagues analyzed 54 articles concerning the evaluation of MRI that were published between 1980 and 1984, early after the introduction of the technique, by using ten commonly accepted criteria for adequate research methodology.³⁸ They found that five fundamental indices of efficacy—sensitivity, specificity, false-positive or false-negative results, accuracy, and predictive value—were used infrequently, and that fewer than 20% of the publications employed three of these terms appropriately. Only 22% compared the MRI results with an independent 'gold standard' such as surgery or autopsy. In 63% of studies another imaging procedure was employed as the reference standard, and only one study was prospective. None of the studies used appropriate statistical methodology such as randomization or measurement of observer error. Cooper et al. concluded that those paying for such expensive new diagnostic technology should demand better research in diagnostic efficacy. A later study by Taylor and colleagues in 1993 examined a sample of 146 publications from two radiology journals;³⁹ three physician reviewers categorized the articles according to phase, modality, and design. Research in MRI comprised 45% of the publications and was oriented to phase 1 (32%) rather than phase 5 (0%) studies. Only 27% of 48 diagnostic-efficacy studies were externally funded. Taylor et al. concluded that analysis of research trends requires a standard taxonomy, which adopts a modality-based, phased approach. Assessment of the clinical efficacy of diagnostic imaging technologies frequently involves reviews of published research. Reports may be classified in three dimensions: by disease, by type of assessment, and by the quality of the research methods employed. The disease dimension describes the condition or conditions shown by an imaging technique. The assessment dimension spans five levels: technical capacity, diagnostic accuracy, diagnostic impact, therapeutic impact, and patient-outcome impact. The methods-quality dimension can be expressed as four levels: excellent, good, fair, or poor. An important interaction exists, in that the level of efficacy addressed by a research project dictates which methodological procedures are important. For example, randomization is important only when a research report addresses the levels of therapeutic and patient outcome impacts. Taylor et al. suggest that classification of studies according to the three proposed dimensions maps the breadth (across diseases), depth (across levels of clinical efficacy), and quality of the assessment of complex imaging technologies. Such a map should

help participants in technology assessment define the progress they have made. The authors illustrated their classification strategy by applying it to assess the clinical efficacy of MRI in diagnosis of neurological disease.

Another major question concerns the likelihood that objective assessments of patient-outcome (level 5) efficacy will substantially influence physician behavior in the utilization of diagnostic tests, at least without strict oversight by the insurers of health care costs. Although reliable diagnostic information may improve patient outcomes, it is clear that physicians engage in many activities that appear to have little effect on outcome, especially in dealing with chronic diseases and malignancies. For example, it is difficult to show that outcomes are improved by routinely searching for the unknown primary tumor in patients with known metastatic cancer.⁴⁰ Nonetheless, many physicians do just that. Rigidly controlled scientific studies are required to substantiate or refute suspicions of this kind. However, such clinical trials must meet appropriate standards of medical ethics and will require a delicate balance in their design and interpretation.

For the immediate future, there is an increasing need for scientific studies that measure and compare the efficacies of diagnostic imaging examinations in appropriate clinical settings.⁴¹ These studies will require more and higher quality data in all of the phases through which diagnostic technology evolves and for all of the levels at which diagnostic efficacy can be evaluated.

5 OVERVIEW

Radiologists, like all physicians, have resisted accountability assessment. Historically, new imaging technologies have not been evaluated adequately before they have been used widely. Radiologists are not trained to conduct rigorous efficacy analyses, and reimbursement and other political issues may have been underestimated. However, lessons learned from the past should help in developing improved plans for the careful research that is now sorely needed in the field.

Rigorous, yet practical, methodology must be developed, investigators must be trained, and standard protocols must be designed. Moreover, successful completion of efficacy studies requires the establishment of experienced *teams* of investigators. Radiologists should be deeply involved in the process of outcomes research, and they must cultivate the capacity to build a multidisciplinary team which has the skills and perspective necessary for success. In addition to radiologists, these teams should include referring physicians, medical physicists, biostatisticians, epidemiologists, full-time research assistants, and perhaps individuals with expertise in other areas such as computer science and health care economics. Advice of external consultants with expertise in efficacy research should be sought periodically, particularly during the early stages of each team's development. The targeting of areas for study is equally critical; usually it should focus on technologies and settings where the greatest clinical impact is most likely and, at least initially, where objective demonstration of value will be relatively easy.

The task of technology assessment is complex and expensive, but current trends in health care funding require that it be done—and done well.

Quality Control and Quantification in Whole Body MRI and MRS

Hammersmith Hospital, London, UK

1 INTRODUCTION

A whole body system is one used for clinical investigations and studies of living human subjects. The studies may be of any part of the body. A whole body system includes the machine itself plus associated equipment and the mode of use. A whole body system may be used for magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), or both.

Quality control means

1. ensuring that an individual system performs in a way that consistently gives reproducible results that render good clinical value and provide a basis for improving techniques;
2. ensuring that any system gives results conveying the same clinical interpretation as other systems for the same mode of use, so that comparisons of diagnoses and clinical opinion can be made, trained staff can apply their skill generally, new techniques can be propagated, and the body of useful knowledge increased.

1.1 Necessity for Quality Control and its Evolution

Quality control is needed because whole body systems do not automatically perform to give the desirable results referred to above. Nor does any one system automatically convey the same interpretation as others.

Examples of poor results from checks on systems and comparisons between them are shown in Figure 1. Progress occurs through improvements in equipment and techniques, combined with local quality control, and the analysis of clinical results that are reproducible and made comparable by controlled calibration.

For NMR characteristics such as relaxation times, spin density, and chemical shift, pressures have grown for the development of methods for quality control. The pressures come from users (both clinical and scientific), from suppliers, and from government agencies. Users want quality control for improving performance and clinical usefulness, and so do sup-

pliers, together with the public demonstration of high quality. Government agencies want quality control to ensure safety and value for money.

The evolution of quality control is an iterative process, because all the details of a method cannot be clear when work begins, and because practical advantages and disadvantages cannot all be foreseen. There have been several lines for developments in quality control of whole body systems.

Government agencies in individual countries were faced with responsibilities for approving the purchase of the new systems and judging performance. Progress was made in many countries, and in the United States the suppliers' organization (NEMA) produced standard methods for selected parameters.¹⁻⁴ Manufacturers needed methods for checking performance during development, before despatch, and on site. Such methods were the basis of the NEMA standards. The international standards body, IEC, is adopting some of the methods as tests of compliance with health and safety requirements.⁵

In the European Community, NMR Concerted Actions, mainly of users, ran from 1984 to 1996.⁶⁻⁸ These Actions, which had useful interactions with individual manufacturers and with NEMA, went through the repeated iteration of steps for defining the parameters to be measured, creating test objects and substances, specifying protocols, and assessment in practical trials.⁹⁻²¹ The methods were then tested in quantitative studies of selected organs.²²⁻²⁴ The EC Concerted Action standard methods and test objects have been available and used in Europe and elsewhere.

1.2 Physical Basis and Practical Requirements for Quality Control

Whole body systems can use NMR features to define the position of tissues and also to establish their characteristics. The link between characteristics and positions is the NMR signal. These signals are dependent on basic parameters and functions, and the measurement of these is part of quality control. However, it has been found that tests using simulations of actual use are necessary.

The purpose of the test objects and methods is to define absolutely and separately the characteristic and the position. Quality control with test objects then assesses performance in stimulation and detection of the signal. However, the complexities of whole body systems makes clear separation difficult, and interpretation of tests is not straightforward.

A general practical requirement in quality control is that the results can be obtained in an acceptably short period of time, by using the normal clinical operating modes of the system. The methods may, however, require the use of additional computer software.

Quality control is of value only if the finding of any deficiency is followed up by effective action. The control tests, the recommended actions, and the outcomes should be systematically recorded.

2 MRI: TEST PARAMETERS AND PROTOCOLS

Most of the MRI test parameters need different features in the relevant test objects. The use of a standardized set of test

Figure 1 (a) Low-quality uniformity profiles and (b) gross geometric distortion in MRI. (c) Measurements of selection efficiency (Esel) and contamination (Con) in volume-selected proton MRS, using STEAM with $TE = 270$ ms. ((a) and (b) reprinted with permission of Pergamon Press, Oxford, from R. A. Lerski et al., *Magn. Reson. Imaging*, 1988, **6**, 203, 205. objects^{9,11} in combination with the test procedures offers some clear advantages to the users of MRI equipment, especially when these methods have been validated in multicenter trials performed on different MRI systems.^{10,12} Some protocols (NEMA) provide only recommendations on the essential requirements for test objects. These requirements¹⁻⁴ are expressed primarily as the geometry and NMR characteristics of the signal-producing volume, together with definitions for the specification volume and area and the measurement region of interest (ROI).

Key parameters for assessing performance in quality control are signal uniformity, geometric distortion, signal-to noise ratio,

slice thickness, and profile. Additional important parameters are spatial resolution, signal linearity, uniformity of image signal-to-noise ratio, slice position and warp, and image contrast-to-noise ratio. Of particular importance for quantitation and diagnosis of malfunction are T_1 , T_2 , and spin density precision and accuracy.^{9,11} Deviations of these parameters from their expected values indicate malfunction or erroneous calibration of instrument components.

Key parameters are described below, together with their value for assessing performance and the basics of measurement. It is worth noting that there are three aspects of variation

of signal across the image of a uniform test object: uniformity, artifacts, and signal-to-noise ratio.

Uniformity of image signal refers to the ability of the equipment to produce an image with identical signal response over one plane from a test object with uniform NMR characteristics. This parameter, which characterizes the low-spatial-frequency nonuniformities (i.e., non-noise) typical of MRI, may be affected by main field and rf inhomogeneities, rf penetration and coil geometry, gradient field nonlinearities, inadequacies in gradient pulse calibration or eddy current corrections, irregular response of the rf receiver, and signal processing.^{2,11}

Uniformity is given by pixel variations within the full ROI occupied during clinical use. The parameter can be quantified as the deviation in the image signal intensity relative to the midrange pixel value in the profiles derived from scans in both the phase-encoding and frequency-encoding directions.

Geometric distortion is the deviation between measured distances in an image and the actual corresponding dimensions in the object (allowance being made for magnification).

This parameter (produced by factors such as field inhomogeneity, gradient defects, or signal sampling imperfections^{3,11}) is derived by measuring the distances between fixed points in the image of the test object and determining their deviations from the respective expected values. These deviations are measured in the three orthogonal planes centered at the isocenter.

Image signal-to-noise ratio (S/N) represents the mean of the pixel values over the ROI divided by their standard deviation. This noise is the random variations in pixel intensity. It affects the clarity of MR images and is also an index of hardware performance.^{1,9-11} Changes in image S/N values may occur as a consequence of variations in system calibration, gain, coil tuning, rf shielding, etc.

To simulate image noise in a typical clinical situation, the rf receiver coil must be electrically loaded. Loading may be accomplished by the test objects themselves or with accessories, or by the use of inductive damping loops that can be adjusted for the loaded Q of individual machines.^{1,11} The use of nonstandard test objects that provide some loading for a system may provide a convenient tool for routinely checking the S/N of equipment. Results acquired on different types of system may not, however, be comparable unless standardized test objects and loading procedures are applied.¹¹ The problems of loading are very important and difficult to solve with complete satisfaction.

Slice thickness is the width at half-maximum of the *slice profile*, which itself is the variation in contribution to the image signal as a function of position orthogonal to the plane. It expresses the variation in effectiveness of the selective excitation process through the slice. The slice thickness depends on the rf pulse shape and sequencing, rf field homogeneity, the selection gradient and other parameters. Although slice selection attempts to achieve reception of signal solely from a slab of rectangular profile, the selected slice may have a profile quite different from the ideal. The slice profile can be assessed either by direct measurement with a thin inclined slab of signal-producing material, or by numerical differentiation of the measured edge response function from an inclined surface of an inert wedge immersed in a signal-producing material.^{4,9-11}

Spatial resolution is usually pixel-limited, but several features may lead to a loss of resolution. It is, for instance,

degraded by filtering the raw data through a function used for reducing the image S/N. Eddy currents produced by rapid gradient switching will lead to uneven resolution loss throughout the imaging field. In 2D FT MRI, the frequency-encoding and phase-encoding resolutions will differ, since the sampling and filtering in these directions are independent. Spatial resolution can be measured by determining the minimum bar separation detectable in the image of a bar pattern of varying spacing.^{9,11} The image profile available on most systems may be used to measure the modulation across a particular set of bars. Spatial resolution can also be assessed from an edge-containing test object, by calculating the modulation transfer function (MTF) associated with the obtained edge spread function.¹¹

In addition to the above parameters, *signal linearity* represents the linearity of the relationship between image signal and the concentration of the excitation-sensitive material. This can be measured with the use of a test object including a series of tubes containing substances with different spin densities.

Uniformity of image signal-to-noise ratio measures the variation of image S/N over one imaging plane, obtained from the same test object utilized for S/N, while *slice position* and *slice flatness* or *warp* jointly describe defects in the selection and expression of planar slices. They can be measured with the same test object.^{9,11}

T_1 , T_2 , and *spin density precision and accuracy* are the basis of the contrast in MRI images, without which they have no clinical value. Their long- and short-term precision is therefore worth study and control.

Many centers are also interested in the accuracy of T_1 , T_2 , and spin density, for both clinical and scientific reasons. The accuracy of measurements with the whole body system is the closeness with which parameter values correspond to the known values of standards that have been separately calibrated.^{9,11}

2.1 MRI Test Objects

As mentioned above, NEMA gives recommendation on some of the features needed for suitable test objects. These recommendations are similar to the detailed final designs worked out and tested by the EC Concerted Action (Figure 2).

2.2 Levels of Quality Control in MRI

There are several levels of quality control appropriate for different circumstances. When receiving a new machine, complete acceptance tests should be done, preferably in the presence of the manufacturer or the supplier.

Periodic maintenance requires tests less detailed than acceptance tests, but more extensive than those for routine application by users. The latter need to be acceptably rapid and to provide control, particularly of signal quality and geometry.

One of the most critical performance indicators is S/N. It is necessary to measure this frequently, because it is easy to lose signal or gain noise. The quality of image is also critically dependent on optimal adjustment of rf pulses and sequence timings, and it is important that these should be checked on a regular basis. For all tests, it is necessary to have a series of techniques with standard protocols, so that each performance feature may be measured and compared with least effort and time.

Figure 2 MRI test objects designed and constructed by the EC Concerted Action for quality control in whole body clinical systems:⁹⁻¹² TO1 [uniformity of image signal; image S/N; uniformity of image S/N; artifacts (ghosting)]; TO2 (geometric distortion; slice profile; slice thickness); TO3 (slice position; slice warp); TO4 (spatial resolution; modulation transfer function); TO5 (T_1 , T_2 , and spin density accuracy and precision; signal linearity; image contrast-to-noise ratio). The annulus represents one approach to providing appropriate loading for measuring S/N. (Schemes of test objects are reproduced with permission of Pergamon Press, Oxford, from R. A. Lerski et al., *Magn. Reson. Imaging*, 1993, **11**, 837. Photograph of test objects courtesy of R. A. Lerski)

3 MRS: TEST PARAMETERS, TEST OBJECTS, AND PROTOCOLS

While the same basic procedures in principle might be used (with appropriate adaptations) for MRI and *magnetic resonance spectroscopic imaging* (MRSI),²¹ for single volume spectroscopy, where only one volume of tissue is under study, additional and different tests are needed.¹³

For single volume spectroscopy, the localization performance is the important factor for many of the parameters. *Localization* is the process of maximizing signal from the single volume that is the object of study and of restricting signals from outside. There are many useful techniques used for localization but none are ideal.

A simple approach that does not put much demand on the MRS equipment and software is to employ a test object having two compartments (an inner and outer one) for the localization testing,^{13,15-18} and to use standard bottles and spheres for some

other tests. The inner and outer compartments may each contain a substance with a single NMR line, but with different chemical shifts. The relative intensities of the two lines in the spectrum then vary as the size and position of the localized volume of study varies with respect to size and position of the two compartments.

It should be noted that some of the parameters below are also relevant to techniques that do not employ localization.

3.1 Test Parameters

Linearity is the linearity of the relations between signal strength and concentration, and signal strength and volume.

Spectral resolution is the full linewidths at one-half and at one-tenth of the maximum peak height for the spectral peaks from the inner and outer compartments. To assess the effect of the measuring sequence, this test can be performed with and without localization.

The *signal-to-noise ratio* (S/N) is measured per unit concentration in a fixed volume.

The *selection efficiency* is the ratio of the signal strengths from the inner compartment with and without localization. This parameter indicates signal loss due to the applied localization sequence. Ideally, its value equals one if the selected volume is isocentric with and equals or exceeds that of the inner container. In practice, this signal loss will depend on the ratio of the selected volume and the inner compartment volume, and should therefore be determined for various ratios.

The *extra volume suppression factor* is the ratio of the signal strengths from the outer compartment without and with localization. This parameter quantifies unwanted signal leakage from outside into the selected *volume of interest* (VOI). Ideally, its value is unity if the selected volume is centered in and smaller than or equals the volume of the inner container. Owing to imperfect slice profiles, it will depend on the ratio of the selected and the inner compartment volumes. It should therefore also be measured for various ratios.

Contamination is the ratio of the unwanted signal from outside the VOI and the total signal in the spectrum. This is a less fundamental localization performance property than the suppression factor and selection efficiency. It depends on the relative volumes of and the concentrations in the two compartments, and it directly expresses the percentage of unwanted signal in the spectrum, using the actual pulse sequence and VOI.

The *VOI profile* characterizes the slice profile in one, two, or three dimensions. Ideally, the profile should be plotted and specified, for instance by the full width at 20, 50, and 80% of the maximum signal height. The profile can be determined using imaging methods.

The *accuracy of the VOI position* is the deviation between the position of the center of the VOI, as determined with a test object and procedure, and the true position. An imaging method can be used, after performing the imaging quality control tests.⁹ The VOI center is estimated from the slice profile.

Selective suppression of signals in the spectrum is the ratio of the signal strength without and with suppression, obtained from two localized experiments, with and without suppression of the signal of the inner compartment. This parameter can be used to test the effectiveness of suppression methods (e.g., for water and fat), and with spectral editing.

For assessing the *stability* of localization, an experiment is repeated several times. The average value of the strengths of the signals from the two compartments and their standard deviations are determined. This test can be used to assess the short- and long-term stability of the equipment.

Precise descriptions of the implementation of the tests to determine the parameters indicated above, and more detailed information about the parameters themselves and other quantities involved, can be found in the literature.^{13–18}

3.2 Test Objects and Substances

Substances are needed for constructing and filling test objects. For single volume spectroscopy, the two-compartment object is very useful (Figure 3). The inner compartment is usually a rectangular volume, since most methods localize this shape. For shimming reasons, a sphere as outer compartment is advisable for proton MRS, and a material with a favorable dia-

Figure 3 Test object designed and constructed by the EC Concerted Action for quality control of volume selection in whole body MRS systems.^{13,15} (Courtesy of Dr. S. F. Keevil)

magnetic susceptibility should be chosen from which to construct the test objects. Plexiglass is therefore to be preferred to glass. Moreover, it is less fragile—but it is not inert, and therefore imposes restrictions on the choice of the substances for filling the compartments.

The substances used to fill the two compartments should, as far as possible, meet requirements that are sometimes conflicting.

1. The NMR spectrum of a substance should be a single line.
2. The chemical shift difference between the compounds in the two compartments should be sufficient to minimize line overlap in the spectrum, but also small enough to minimize localization artifacts when selecting slices or volumes by means of frequency-selective pulses and gradients.
3. The relaxation times T_1 of the two lines should be equal, as should be the T_2 values; both should be in the range of *in vivo* values. Doping with paramagnetic substances can sometimes give the desired relaxation values. If suitable values cannot be obtained, equal T_1 values are to be preferred for assessing the quality of localization obtained by using ISIS sequences in ^{31}P MRS. For ^1H MRS, equal T_2 values are preferable, because, in general, echo techniques are employed for localization.
4. If possible, the compounds should be easily available, not poisonous, not flammable, stable, and have relaxation times with a weak temperature dependence and chemical shift values with none.

Details are given by Keevil et al.¹⁷

The field of MRS is still in development, and new techniques evolve. Therefore quality control needs continued adaptation to extend its application to innovative techniques, including spectroscopic imaging.²¹ Quality control, which should be used to check and calibrate apparatus and techniques regularly, represents an essential requirement for absolute metabolic measurements by *in vivo* MRS.²⁴

3.3 Data Analysis

In vivo MRS data do not have a high signal-to-noise ratio, and considerable line overlap occurs. As a consequence, data

analysis methods have to be chosen very carefully. Several quantification methods exist, which may lead to widely varying results, owing to systematic and operator-dependent errors. Model function fitting is the best way to quantify the data and minimize these errors. The effect of the pulse sequence and the data analysis method can be checked using test objects and standard solutions. The results can be incorporated as prior information in the data analysis method, which significantly decreases the systematic errors and the standard deviation.^{13,19,25,26}

Inversion-Recovery Pulse Sequence in MRI

Graeme M. Bydder

University of London, London, UK

1 INTRODUCTION

The inversion-recovery (IR) pulse sequence has been used to provide heavily T_1 -weighted images since the earliest days of clinical MRI. They were used in the first studies which showed an advantage of MRI over ultrasound¹ and computed tomography (CT).² The sequence produced high contrast between normal tissues and pathological tissues which had a prolonged T_1 , and was the single most effective imaging technique available from 1980 to early 1982.

The introduction of the heavily T_2 -weighted spin echo sequence into clinical practice in 1982³⁻⁵ provided a very useful approach to disease detection based on differences in T_2 , and has since become the mainstay of clinical diagnosis in many regions of the body. T_1 -weighted spin echo sequences also provide a method for obtaining T_1 -weighted images which are lower in contrast than inversion-recovery, but are quicker.

MRI studies in 1980 to early 1982 involved only a single slice and were performed at low fields (0.04–0.15 T). After this time there was a general tendency to increase operating field strength, which increases tissue T_1 and prolongs the time required for the IR sequence for equivalent image contrast. Multiple slice techniques were also developed at this time, and these required slice selective 180° pulses. While slice selective 90° pulses were easy to implement, it took some time to achieve this with 180° pulses. Also, the IR sequence with its relatively long interval between the initial 180° pulse and the subsequent 90° was more difficult to interleave into a multi-slice format than conventional spin echo sequences.

For these reasons, the conventional IR pulse sequence was displaced as the principal pulse sequence used for diagnostic purposes, but it continued to have many applications when high T_1 -weighted contrast was desired, such as in detecting contrast enhancement^{6,7} or in demonstrating early myelination in infants.^{8,9}

A particular variant of the IR sequence in which the timing of the initial inversion pulse was set to null the signal from fat (which has a very short T_1) and TE was chosen to provide very high contrast images proved to be very useful in body and orthopedic applications.^{10,11} This short inversion time IR (STIR) sequence combined fat suppression with high lesion contrast and did not require careful shimming as with frequency selective techniques. At a time when some orthopedic, bone marrow and oncological applications were difficult, it proved a valuable addition to MRI and remains in active use at the present time. It is particularly suited to mid- and low-field applications where chemical shift techniques for fat suppression are difficult.

The capacity of the IR sequence to null fluids has also been exploited in the form of the fluid attenuated inversion-recovery (FLAIR) sequence where cerebrospinal fluid (CSF) is suppressed and heavy T_2 -weighting (long TE) is used to detect lesions in brain and spinal cord.¹²

Both fluid suppression and fat (or white matter) suppression can be combined in the form of the doubly attenuated inversion recovery (DAIR) sequence, which can be used, for example, to isolate the cerebral cortex or to demonstrate liver pathology.¹⁰ Inversion pulses have also been used to label inflowing blood outside of the slice of interest as a measure of tissue perfusion.¹³

With the development of faster imaging techniques for clinical use, such as the rapid acquisition with relaxation enhancement (RARE) sequence,¹⁴ the rapid gradient echo,^{15,16} and echo planar imaging,¹⁷ there has been renewed interest in the use of the IR sequence. With these sequences the time penalty associated with the sequence is no longer felt so acutely. Many of the faster sequences have unfavorable contrast properties which can be modified to make them useful by application of an appropriately timed inversion pulse prior to the data collection. The clinical uses of these sequences parallel those previously developed with slower versions of the IR sequence, but have the advantage that they can be performed much more rapidly.

In the following section the basic form of the IR sequence will be described, followed by outlines of the STIR, FLAIR, other forms of the IR sequence, and fast variants.

2 THE BASIC FORM OF THE IR SEQUENCE

The dependence of signal intensity seen with the IR sequence on proton density, T_1 and T_2 can be described in mathematical terms using the Bloch equations, but a qualitative description of the IR sequence will be used in this section. The proton magnetization induced in the patient by the static magnetic field can be represented by a vector $\mathbf{M}$. The component of the magnetization in the transverse plane at any given time is then represented by M_{xy} , and that in the longitudinal direction at the same time by M_z . The effect of a 90° pulse is to rotate M_z into the transverse plane to become M_{xy} .

Following a 90° pulse, M_z increases exponentially from zero with time constant T_1 [Figure 1(a)], and M_{xy} decays exponentially with time constant T_2 [Figure 1(b)]. At the following 180° pulse M_z is inverted to become $-M_z$ and recovers with a time constant T_1 , but at twice the rate for the earlier longitudinal recovery after the 90° pulse. At the next 90° , pulse M_z is rotated to become M_{xy} . M_{xy} then decays exponentially with time constant T_2 . Using a gradient echo or spin echo data collection, the signal is collected at a mean time TE after the 90° pulse, and the cycle is repeated.

A composite diagram following firstly M_z then M_{xy} after the second 90° pulse can be used to represent the 'potential signal intensity' at various stages in the sequence [Figure 1(c)]. The size of the received signal and, ultimately, the signal intensity or pixel value in the image is proportional to M_{xy} at the time of the data collection (DC). M_{xy} is also proportional to tissue proton density.

The times TI and TE are shown in Figure 1(c). TI is the inversion time between the inverting 180° pulse and the fol-

Figure 1 Changes in M_z (a) and M_{xy} (b) with time in the IR sequence (medium TI) using a field echo data collection (DC). Figure 1(c) shows M_z initially then M_{xy} in the last segment

lowing 90° pulse, and TE is the time from the last 90° pulse to the following echo. Repetition time (TR) is the duration of each cycle of the sequence.

Using Figure 1(c) as a model of the IR sequence, we can next compare the signal intensities of white matter (a tissue with a relatively short T_1), gray matter (a tissue with a longer T_1), and CSF (which has a very long T_1), as in Figure 2. The signal intensity observed is proportional to the height of M_{xy} at the time of the DC, and it can be seen that the shorter T_1 of white matter results in a higher signal intensity than for gray matter. The very long T_1 of CSF results in a low signal intensity, which may be negative as in Figure 2. The last segment of the decay converges towards zero for both gray and white matter with their positive signal intensities, as well as for CSF with its negative signal intensity. Display of the resultant image after phase corrected processing (see later) gives white signal intensity for white matter, light gray for gray matter, and black for CSF. The signal for gray matter is slightly greater than that for white matter at the time of the 180° pulse because of its greater proton density.

The general rule is that a TR of at least $3T_1$ should be allowed for recovery of the longitudinal magnetization between the final 90° pulse of one cycle and the initial 180° pulse of the next pulse cycle to allow a high level of recovery of M_z , though, in practice, it may be possible to use times less than this. Reducing TR produces a reduction in signal intensity for

tissues with a long T_1 , though there is little effect on tissues with a short T_1 where TR is still greater than $3T_1$. Reducing TR is therefore used to reduce the relative signal intensity of tissues or fluids such as CSF which have a very long T_1 .

There are two types of image reconstruction available: (1) phase corrected, where positive values of signal intensity are shown positive and negative values appear negative; and (2) magnitude reconstruction, where the magnitude of the signal is used irrespective of its sign. In the above sequences the CSF appears dark with phase corrected processing but may show a 'rebound' with a lighter central area with magnitude processing. The signal intensities follow directly from considering Figure 2.

The 90° pulse in the IR imaging sequence is always slice selective, though for single scans the 180° pulse(s) need not be. However, when the inversion-recovery sequence is used to obtain an interleaved set of slices, the 180° pulse(s) must be slice selective. When the 180° pulse is slice selective, it is possible for flowing blood to experience only part of the IR sequence, depending on where it is at the time of the inversion pulses. For example, blood flowing into a slice may only experience a 90° pulse and behave as though it is being imaged with a partial saturation sequence, producing a high signal intensity rather than the usual low signal intensity.

It is useful to consider three main variants of the IR sequence according to their values of TI :

1. the medium TI inversion recovery sequence;
2. the short TI sequence; and
3. the long TI sequence

These will be dealt with in the next sections.

3 THE MEDIUM TI IR SEQUENCE

The working rule to obtain an image with good contrast between two tissues of different T_1 values is to choose a value of TI intermediate between the two tissues of interest (neglecting the effects of proton density and T_2). Thus, satisfactory contrast between white matter ($T_1 = 350$ ms) and gray matter ($T_1 = 450$ ms) is achieved with a TI of about 400 ms at a field of 0.15 T. Note that the signal intensity is not maximal at this point, so the image appears noisier than that obtained with, for example, $TI = 500$ ms where the signal is higher (although the

Figure 2 Changes in M_z/M_{xy} with time in the IR sequence (medium TI) for white matter (W), gray matter (G), and CSF using a field echo data collection (DC). The signal intensity on the image is proportional to the height of M_{xy} at the middle of DC. White matter is highest, followed by gray matter, then CSF

Figure 3 Cerebral infarction in an infant aged 9 months: Transverse IR3400/30/800 (IR $TR/TE/TI$) scan. The white matter (partially myelinated) is white, the gray matter is gray, and the infarction (arrow) is black

gray-white matter contrast is less). In theory, maximum contrast is obtained when TI is about 0.6 times the average of the T_1 for the two tissues, but the signal levels in this case are close to zero, so maximizing the appearance of the noise of the image. Note that the TI for optimum contrast between gray matter and a tumor or an infarct (which have an increased T_1) is greater than that for gray and white matter. These features are illustrated in Figure 3, which shows a cerebral infarct in an infant aged 9 months. White matter is white, gray matter is gray, and the infarction is dark, using phase corrected processing.

There are two additional modifying factors. The increased mobile proton density of gray matter relative to white matter results in slightly less tissue contrast. More important is the fact that the T_2 dependent period following the 90° pulse and prior to data collection may produce a reduction in tissue contrast. This is particularly so for lesions which follow the common pattern and have an increase in both T_1 and T_2 . Thus, the T_2 dependent decay, in the last component of the sequence, reduces the T_1 contrast developed earlier in the sequence.

The method of image reconstruction and the type of data collection affect TE . TE can generally be shorter with projection reconstruction than with 2D Fourier transformation since a single vector encoding gradient is used, without the need for a previous phase-encoding gradient as with 2D Fourier transformation. A gradient echo data collection can be completed earlier than a spin echo collection with the same bandwidth,

although the former is more vulnerable to B_0 field inhomogeneities.

With the brain (T_2 about 100 ms) the T_2 dependence of the IR sequence is not such a big problem as it is in the body, where values of T_2 are typically half of those in the brain (45–60 ms), making the same IR sequence much more T_2 dependent than when it is used in the brain. The use of short values of TE to control this problem then becomes important. Figure 4 shows a transverse CT image of the liver in which a metastasis is shown in the quadrate lobe (large arrow) but an additional lesion with a long T_1 value is seen in the liver with the IR sequence (small arrow).

4 THE SHORT TI IR (STIR) SEQUENCE

Values of TI under discussion here are about 0–250 ms. In the limit where TI equals zero (or, from a practical point of view, about 1 ms) the 90° and 180° pulses add, to give a 270°

Figure 4 Metastases in the liver: (a) transverse contrast enhanced CT and (b) IR1400/10/400 scans. One metastasis is seen with both scans (large arrow), but another (small arrow) is only seen with the IR scan (b)

Figure 5 Changes in M_z/M_{xy} with time for the STIR sequence. The size of the signal from gray matter (G) is greater than that for white matter (W). When magnitude processing is used, it has a higher signal

pulse which is equivalent to a -90° pulse. This is equivalent to a 90° pulse, and the sequence becomes 90° data collection, or the partial saturation (PS) sequence. Thus the PS sequence can be regarded as a limiting case of the IR sequence with $TI = 0$. The same reasoning applies when a spin echo data collection is used and the IR sequence (with $TI = 0$) becomes equivalent to a spin echo sequence. Using magnitude reconstruction with TI in the range of 0 to about 250 ms, an IR image of the brain appears like a spin echo one, although with greater gray–white matter contrast. The magnetization curves can be represented as shown in Figure 5.

Note that following the final 90° pulse the T_1 contrast and the T_2 contrast are additive, i.e. increasing the T_1 of a tissue increases the tissue's relative signal intensity and so does increasing its T_2 . (This is not the case in Figure 2, which illustrates medium values of TI .) The short TI IR (STIR) sequence is sensitive to changes in T_1 and T_2 , and can be used as a screening sequence in the brain in a similar way to the spin echo sequences with long TE and long TR such as SE1500/80.

Figure 6 Changes in M_z/M_{xy} with time for fat (F), white matter (W), and gray matter (G) using a fat suppressed STIR sequence. The signal from gray matter is greater than that from white matter. Fat gives no signal

Figure 7 Recurrent liver metastases and para-aortic tumor: (a) transverse SE544/44 and (b) IR1500/44/100 images. The liver and para-aortic lesions show low contrast in (a) but are highlighted in (b) (arrows). Fat gives no signal in (b)

To reduce the signal intensity of CSF to less than that of white matter, TR can be shortened to 1000 ms with a sequence such as IR1000/44/100 (at 0.15 T).

Since many pathological lesions produce an increase in both T_1 and T_2 , the addition of these two types of contrast with the STIR sequence produces a high net tissue contrast. This type of sequence also enables some T_1 dependent decay to be substituted for the T_2 dependent decay in the equivalent spin echo sequence. This is of particular value where the T_1 and T_2 decays of the tissues differ and explains why the gray–white matter contrast of this sequence is greater than that of the equivalent spin echo sequence.

It is also possible to choose particular values of TI so that the signal intensity of a particular tissue is zero at the time of the 90° pulse. (This occurs at a value of TI typically between 0.56 and 0.69 T_1 for $TR > 3T_1$.) Values of about 100 ms are suitable to eliminate the fat signal, while 255 ms is adequate for white matter (Figure 6). In this situation the tissue signal is said to be ‘suppressed’. Suppression or partial suppression of

Figure 8 Bilateral avascular necrosis of the hips: coronal IR2500/30/140 scan (at 1 T). The pathological regions in the heads of both femurs and the adjacent acetabulum and muscle on the left are highlighted (arrows)

the fat signal is of particular value in imaging of the orbit, body (Figure 7) and musculoskeletal system (Figure 8), and this is the most common use of the STIR sequence.

5 LONG T_I OR FLUID ATTENUATED INVERSION-RECOVERY (FLAIR) SEQUENCE

If the T_I is increased to 2000–2500 ms, then the signal from CSF can be reduced to zero while the magnetization from brain

Figure 9 M_z followed by M_{xy} for brain (B) and CSF during the FLAIR sequence. Following the first 90° pulse, the brain recovers more quickly than the CSF. After the 180° pulse brain largely recovers, but CSF with its long T_1 only reaches zero magnetization when the second 90° pulse is applied. Brain then decays with time constant T_2 while the CSF signal remains zero

very largely recovers (Figure 9). With the signal from CSF very greatly reduced, it is then possible to use the echo times of 120–200 ms and develop very heavily T_2 -weighted contrast without problems from CSF artifacts.

The resultant FLAIR sequence has been used to image the brain in multiple sclerosis (Figure 10), hippocampal sclerosis (Figure 11), and many other conditions.

It is particularly useful in regions of the brain where partial volume effects from CSF cause difficulty. Its reduced gray–white contrast (as a result of incomplete recovery of the brain magnetization) provides a bland background against which lesions are readily seen. The same principles apply to the spinal cord, where lesions with a long T_2 are readily seen (Figure 12).

6 OTHER FORMS OF THE IR SEQUENCE

The DAIR sequence combines features of the FLAIR and STIR sequences (Figure 13). It can be used to null the signal from CSF as well as from fat, white matter, or gray matter (Figure 14).

The same principle can be applied to null the signal from bile (very long T_1) and fat in the abdomen (Figure 15).

It is also possible to apply an inversion pulse outside of the imaging plane and detect the change in magnetization within the slice as the inverted magnetization is carried into the slice by flowing blood to provide a measure of perfusion. The effect depends on the T_1 of the blood, the position of the slice, the field strength, and other factors.

7 FASTER FORMS OF THE IR SEQUENCE

The RARE sequence, in which more than one phase-encoding step is used after each excitation,¹⁴ enables the imaging time to be reduced. It can be combined with each form of the IR sequence and can result in a substantial reduction in imaging time. Results with turbo-STIR and turbo-FLAIR sequences of this type have now been published.

The rapid gradient echo sequences can be used to acquire data in 1 or 2 seconds. When these are preceded by a 180° pulse they also provide the basic options available with the IR sequence. The term ‘magnetization preparation’ has been applied to the use of not just inversion pulses but pulsed gradients, magnetization transfer, and chemical shift sensitive pulses in this context. The magnetization prepared rapid acquisition gradient echo (MP-RAGE) sequence has proved useful with a medium T_I in producing highly T_1 -weighted volume images of the brain.^{15,16}

The echo planar sequence can¹⁷ be used similarly to exploit the range of T_I values described above.

These forms of the IR sequence are now receiving greater emphasis and are likely to be the forms in which it is used in the future.

Figure 10 Multiple sclerosis: (a) transverse SE2500/80 and (b) IR6000/160/2100 scans. Many lesions are readily seen in both (a) and (b), but some lesions are only seen in (b) (arrow)

Figure 11 Hippocampal sclerosis: (a) transverse SE2500/80 and (b) IR6000/160/2100 scans. No abnormality is seen in the left hippocampus in (a) but it is highlighted in (b) (arrow)

Figure 12 Ependymoma following surgery: (a) sagittal SE2500/80 and (b) IR6000/160/2100 scans. Following surgery the atrophic cord is well seen in (b). There is also a high signal area, which may be residual tumor, edema, or recurrence (arrow)

8 CONCLUSION

Different aspects of each of the given pulse sequences have been described, and simplified approaches to understanding the contrast developed by each of them have been outlined. Considerable effort has been expended in evaluating pulse sequences and adopting them for a particular purpose, but in some ways the most surprising thing has been the ease with which the results can be predicted from these simple models.

Figure 13 The DAIR sequence: M_z followed by M_{xy} . This sequence combines the FLAIR and STIR sequences. Note that after the first 180° pulse the CSF is allowed to recover beyond the null point before being inverted a second time and nulled at the time of the second 90° pulse

Figure 14 Transverse head scan: DAIR sequence IR3000/20/2300/245. The gray matter has been isolated and gives a high signal. The complex folding of the cortex is readily seen

Figure 15 Liver abscess: (a) transverse IR1000/44/100 and (b) IR3000/44/1200/100 sequences. The high signal in the posterior aspect of the liver is shown with both sequences (large arrow). The gall bladder and CSF are shown in (a) (small arrows) but suppressed in (b)

Susceptibility Effects in Whole Body Experiments

Jerrold L. Boxerman, Robert M. Weisskoff
and Bruce R. Rosen

Massachusetts General Hospital, Charlestown, MA, USA

1 INTRODUCTION

This chapter summarizes susceptibility-based NMR image contrast. Susceptibility phenomena can affect MR images on both a *macroscopic* level, which leads to typical image artifacts associated with poor shimming, metallic implants, and susceptibility differences at air–tissue interfaces, and on a *microscopic* level, which has been exploited by dynamic imaging with and without contrast agents in order to quantify tissue hemodynamics and to measure a variety of physiological parameters. In this chapter, we will review our current understanding of the susceptibility contrast physics that underlies these artifacts and applications.

2 THE FUNDAMENTALS OF MAGNETIC SUSCEPTIBILITY

The response of the internal magnetization of a material to an applied external magnetic field is referred to as its *magnetic susceptibility*. Both orbital and spin angular momentum of electrons generate a magnetic field, $\mathbf{B}$. Because magnetic moment is inversely proportional to mass, the nucleus contributes much less to the magnetic properties of the atom than do the electrons, despite having both charge and spin angular momentum. Therefore, whereas nuclear magnetization is responsible for MR signal, electron magnetization determines the bulk magnetic properties of tissue.

2.1 Diamagnetism

Diamagnetic materials include most organic and many inorganic compounds containing low molecular weight elements (C, H) with paired electrons. These materials reduce the magnitude of the external field by induction of an opposing Lenz field. No magnetic field arises from the spin angular momentum of electrons paired according to the Pauli exclusion principle. Paired electrons do have orbital angular momentum, however, and according to Lenz's law, will diminish $\mathbf{B}$ at the center of the orbital by generating a magnetic field that opposes the external magnetic field. Because magnetic moments arising from electron orbital motion are much smaller than those resulting from electron spin, these diamagnetic effects are dominant only in the absence of unpaired electrons which would otherwise overwhelm the effect. Diamagnetism accounts for air–tissue artifacts in the brain and lungs (since the susceptibility of air is near zero), and diamagnetic materials primarily

affect MR signals by displacing normal contents such as water, fat, perfluorocarbons, or CO_2 in the bowel.

2.2 Paramagnetism

Within transition metal ions, like ferrous and ferric oxidation states of iron, gadolinium, and dysprosium, some orbital electrons are unpaired and therefore possess both net spin and orbital angular momentum. When randomly oriented, zero total magnetic field is generated. However, much like the weaker nuclear magnetic dipoles, electron magnetic dipoles respond to an external magnetic field by aligning parallel or antiparallel to the applied field thus producing a net magnetization. Because more dipoles align parallel to the field, the ambient field is enhanced, and this effect dominates the weaker diamagnetic properties when there are sufficient unpaired spins. Materials that enhance the magnitude of the external field in this manner are said to be *paramagnetic*.

For both dia- and paramagnetic materials, the induced magnetic field is proportional to the strength of the applied magnetic field, $\mathbf{B}_0$:

$$\mathbf{M} = \chi \mathbf{B}_0 \quad (1)$$

where $\mathbf{M}$ is the induced magnetization. The constant of proportionality, χ , is positive for paramagnetic materials and negative for diamagnetic materials.

2.3 Superparamagnetism and Ferromagnetism

In *superparamagnetic* materials (such as the contrast agent AMI-227, Advanced Magnetics Inc., Cambridge, MA), whole domains of unpaired spins act together as if they were one large paramagnetic, single domain particle that can reorient its net dipole in an applied field in a time frame that is short compared with the observation time (see *Contrast Agents in MRI: Superparamagnetic Iron Oxide*). In response to an applied field, each domain aligns parallel or antiparallel to the field, analogous to paramagnetic materials, but the resultant magnetic moment for the domain of interacting unpaired electrons is much greater than that for the paramagnetic case. As with normal paramagnetic materials, the induced fields for superparamagnetic materials increase linearly with applied field strength at low fields, but saturate at high fields and return to zero without hysteresis upon removal of the applied field.

Ferromagnetic materials have unpaired electrons aligned in Weiss domains, each with a net magnetic field. The magnetic dipoles of the unpaired electrons of adjacent atoms interact to form magnetically stable configurations, and these adjacent domains interact via their fields to minimize the applied external field. Each domain responds to both the applied and the neighboring domain fields. Orientation of the magnetic dipoles of each domain is along a crystal axis, and the sum of the dipoles for all domains is nonzero. The material therefore has a net dipole even in the absence of an applied field, which renders these materials suitable for use in magnetic recording devices. However, ferromagnetic materials rarely have a useful purpose in MRI, though they can be a source of hazard and artifact.

2.4 Magnetic Susceptibility and MR Images

Depending on the properties of the material, $\mathbf{M}$, induced by $\mathbf{B}_0$, will yield an effective magnetic field $\mathbf{B}_{\text{eff}}$, with an order of magnitude χB_0 , that is either greater than (paramagnetic; $\chi > 0$) or less than (diamagnetic; $\chi < 0$) the applied field. The actual magnetic field will depend strongly upon the geometry of the magnetic material. Nuclear spins precess about the axis of the applied $\mathbf{B}_0$ with an angular frequency ω_0 , defined by the Larmor equation:

$$\omega_0 = \gamma B_0 \quad (2)$$

where γ is the gyromagnetic ratio. An applied field will therefore induce a perturbing field in susceptible materials, which in turn will cause protons to precess at angular frequencies other than ω_0 . This can have profound macroscopic and microscopic effects on MR images.

3 MACROSCOPIC EFFECTS: FREQUENCY AND PHASE SHIFT

Similar to the effects of chemical shift and main magnetic field inhomogeneity, magnetic susceptibility geometrically distorts the MR image and perturbs image intensities. It is instructive to illustrate this from a theoretical perspective^{1,2} by considering a typical two-dimensional Fourier transform imaging experiment, with the main magnetic field and slice selection oriented along z , frequency encode along x , and phase encode along y .

3.1 Geometrical Distortion in the Image Plane

MR signal can be expressed in a k -space formalism as:

$$S(k_x, k_y) = \iint \rho(x, y) e^{-i(k_x x + k_y y)} dx dy \quad (3)$$

where $\rho(x, y)$ is the two-dimensional spin density for a selected slice, $k_x = \gamma G_x t_x$ and $k_y = \gamma G_y T_y$ are defined for frequency and phase-encoding gradients G_x and G_y , respectively, t_x is the time at which a k_x sample is obtained (defined relative to echo time TE) and T_y is the duration of the phase encode gradient. Along a row of k -space in the frequency-encode direction, each sample is acquired at a distinct point in 'real' time, and k_x is varied by sampling the signal for each phase-encode step at incremental times t_x . Along a column of k -space in the phase-encode direction, 'pseudo' time evolves as a function of $G_y T_y$, the product of gradient amplitude and duration. k_y is typically varied by incrementing G_y at each phase-encoding step for a fixed T_y .

The manifestation of susceptibility differences in MR images is apparent when considering how magnetic field inhomogeneities propagate through the imaging equation. The phase that has evolved by each sample in the k_x direction has both a component due to the frequency-encode gradient G_x , and a component due to magnetic field inhomogeneities:

$$\phi = \omega t = k_x x + \gamma \Delta B (TE + t_x) \quad (4)$$

where $\Delta B(x, y)$ is the total field inhomogeneity at spatial location (x, y) and has contributions from static field (ΔB_0), chemical shift-dependent (ΔB_c) and susceptibility-dependent (ΔB_s) inhomogeneities:

$$\Delta B(x, y) = \Delta B_0(x, y) + \Delta B_c(x, y) + \Delta B_s(x, y) \quad (5)$$

The contribution to ϕ from ΔB evolves from the $\pi/2$ pulse to the sample acquisition for a total time of $TE + t_x$, and is therefore a function of t_x . The phase that has evolved by each sample in the k_y direction is also a function of the magnetic field inhomogeneities (included in the $\gamma \Delta B TE$ term above). But because each line of k -space represents a distinct acquisition, phase errors do not accumulate through multiple phase-encode steps, and hence the ϕ that evolves due to ΔB is not a function of 'pseudo' time.

The expression for NMR signal $S(k_x, k_y)$ in the presence of ΔB is therefore given by:

$$\begin{aligned} S(k_x, k_y) &= \iint \rho(x, y) e^{-i(k_x x + \gamma \Delta B(x, y)(TE + t_x) + k_y y)} dx dy \\ &= \iint \rho(x, y) e^{-i\gamma \Delta B(x, y) TE} \\ &\quad \times e^{-i\{k_x [x + \Delta B(x, y)/G_x] + k_y y\}} dx dy \end{aligned} \quad (6)$$

Field inhomogeneity effects are therefore primarily reflected along the frequency-encode direction and spatially transform x to $x + \Delta B(x, y)/G_x$. Consequently, a pixel at position (x, y) will be displayed after Fourier reconstruction at a new position (x', y) , where

$$x' = x + \frac{\Delta B(x, y)}{G_x} = x + \Delta x \quad (7)$$

Spatial displacement is reduced with stronger frequency-encode gradients (larger bandwidth); however larger gradients decrease S/N and increase aliasing artifacts. Techniques using the phase difference between two scans have been described that correct for susceptibility-based geometrical distortions.³

In gradient echo (GE) acquisitions, the $e^{-i\gamma \Delta B(x, y) TE}$ term results in a phase shift throughout the image that reflects the field inhomogeneities and can actually be used to map field inhomogeneities^{4,5} In spin echo (SE) acquisitions, this term vanishes, since the π pulse corrects for static inhomogeneities. In echo planar imaging⁶ (see *Echo-Planar Imaging*), phase errors accumulate in the phase-encode direction because of the continuous readout, and in fact are much more significant than phase errors in the frequency-encode direction because the total acquisition time (~50 ms) is much greater than the read period for any individual line of k -space (~0.5 ms). Phase-encode distortion is thus far more significant than frequency-encode distortion on echo planar imaging.

3.2 Intensity Distortion

If $\Delta B(x, y)$ varies with x , then the signal intensity for the shifted pixel will be attenuated. This is appreciated by considering that a constant amount of signal, originally contained in a pixel with area xy , is now being spread over a transformed pixel with new area $x'y$. The areas are related by:

$$dx' dy = |J| dx dy \quad (8)$$

where J is the Jacobian of the transformation:

$$|J| = \begin{vmatrix} \partial x'/\partial x & \partial x'/\partial y \\ \partial y/\partial x' & \partial y/\partial y \end{vmatrix} = 1 + \frac{1}{G_x} \frac{\partial \Delta B(x, y)}{\partial x} \quad (9)$$

Therefore, the reconstructed spin density ρ' will be related to the original spin density by:

$$\rho'(x', y) = \frac{\rho(x, y)}{1 + \frac{1}{G_x} \frac{\partial \Delta B(x, y)}{\partial x}} \quad (10)$$

If $\partial \Delta B(x, y)/\partial x = 0$, then a spatial shift occurs with no concomitant signal attenuation, assuming that shifted pixels do not overlap with other portions of the image.

3.3 Slice-Selection Error

In the absence of magnetic field inhomogeneities, a frequency

$$2\pi f = \gamma(B_0 + zG_z) \quad (11)$$

is used with an rf excitation to select a slice centered at position z , where G_z is the slice-select gradient. The slice actually selected in the presence of magnetic field inhomogeneities $\Delta B(x, y, z)$ is defined by

$$z'(x, y, z) = z + \frac{\Delta B(x, y, z)}{G_z} = z + \Delta z \quad (12)$$

For a slice-selection rf bandwidth of 1.25 kHz and $G_z = 1 \text{ G cm}^{-1}$, a slice thickness of 3 mm is obtained at 1.5 T. Therefore, magnetic field inhomogeneities on the order of 20 ppm yield a slice-select displacement equivalent to one slice thickness.

3.4 Clinical Examples

Figure 1 demonstrates the geometrical and intensity distortion associated with fast SE ($TR = 4000 \text{ ms}$, $TE = 16 \text{ ms}$) metal artifact in the right parietoccipital cortex from prior surgery. Note the geometry artifact predominant in the frequency-encode direction, and the bright rim due to pixel displacement and overlap.

Figure 2 demonstrates the (a) GE and (b) SE ($TR = 2000 \text{ ms}$, $TE = 120 \text{ ms}$) artifacts due to a ferromagnetic surgical clip at 0.6 T. The artifact on the GE image is far more severe.

4 MICROSCOPIC EFFECTS: LINE BROADENING

Heterogenous distributions of magnetic susceptibility *within* a voxel will cause microscopic perturbations of local proton resonance frequencies by modifying the magnetic field sensed by local spins and can profoundly affect MR signal in three ways:

1. The magnetic field variations can displace intravoxel resonance frequency, resulting in phase shifts for phase-sensitive acquisitions (phase mapping or 'zebra' techniques⁷).

Figure 1 Geometrical and intensity distortion associated with fast spin echo ($TR = 4000 \text{ ms}$, $TE = 16 \text{ ms}$) metal artifact in the right parietoccipital cortex from prior surgery. Note the geometry artifact predominant in the frequency-encode direction, and the bright rim due to pixel displacement and overlap

2. Intravoxel resonance linewidth can be increased by virtue of the diversity of magnetic fields, which decreases MR signal from pulse sequences that do not completely correct for static inhomogeneities (GE and asymmetric SE acquisitions).
3. Diffusion of spins through magnetic field variations introduces nonstatic inhomogeneities and leads to MR signal loss, even for pulse sequences that completely correct for static inhomogeneities (SE acquisitions).

These mechanisms are responsible for the MR signal loss associated with intravascular (IV) paramagnetic chelates (such as Gd-DTPA and Dy-DTPA) that alter dynamically the magnetic susceptibility of tissue during passage through the compartmentalized intravascular space (i.e. in the brain), and for many of the signal changes associated with the extravasation of blood in hemorrhage⁸ (see *Hemorrhage in the Brain and Neck Observed by MRI*) and with iron sequestering diseases. Compartmentalization of agent in these cases induces long range magnetic field perturbations that act at a distance of many micrometers to shorten transiently the T_2 and T_2^* of tissue protons. These perturbations occur in addition to short-range, T_1 enhancement by agents such as Gd-DTPA that occurs when protons diffuse within the coordination sphere of the molecule (see *Contrast Agents in Magnetic Resonance: Operating Mechanisms*).

Figure 2 (a) GE and (b) SE ($TR = 2000$ ms, $TE = 120$ ms) artifacts due to a ferromagnetic surgical clip at 0.6 T. The artifact on the GE image is far more severe

4.1 Susceptibility Contrast Signal Loss

Protons lose transverse coherence as they diffuse through the inhomogeneous magnetic field established by compartmentalized contrast agent, and the transverse relaxation time of the diffusing spins is shortened:

$$\Delta R_2 = \frac{1}{T_{2\text{post}}} - \frac{1}{T_{2\text{pre}}} \approx -\frac{\ln(\text{SA})}{TE} \quad (13)$$

SA is the signal attenuation due to phase dispersion and can be expressed as an expectation of proton phases:

$$\text{SA}(t) = \langle e^{i\phi(t)} \rangle = \frac{1}{V} \int_V d\bar{x} \int d\phi \cdot P(\phi, t; \bar{x}) e^{i\phi(t)} \quad (14)$$

taken over all paths through the medium for each initial proton position, where $P(\phi, t; \mathbf{x})$ is the probability that a proton start-

ing at position $\mathbf{x}$ acquires phase ϕ by time t . $\text{SA}(t)$ depends upon the size of the confining vessels (r), the vascular volume fraction (f_v), the susceptibility difference between agent and surrounding tissue ($\Delta\chi$), and specific pulse sequence parameters. This complex relationship is often inaccessible with analytic techniques and has best been elucidated with numerical methods, such as Monte Carlo techniques that estimate $\text{SA}(t)$ by accumulating the phase from the stochastic walk of many protons through a simulated environment that generates the appropriately distributed set of phases, $P(\phi, t; \mathbf{x})$, in equation (14).^{9–11}

Despite small vascular volume fractions (<5% in cerebral cortex), substantial signal attenuation (up to 50%) reflecting extravascular susceptibility changes are typically realized due to the intravascular compartmentalization of the agent. A clinical example is provided in Figure 3, which depicts the dynamic cerebral passage of a paramagnetic contrast material

Figure 3 Dynamic cerebral passage of a paramagnetic contrast material with high magnetic susceptibility. (a) Six SE echo planar images ($TR = 1$ s, $TE = 100$ ms) from the series (11, 14, 17, 20, 25 and 31 s postinjection) reflect the parenchymal signal attenuation during transit of agent. (b) Complete time course from a cortical region of interest. (Courtesy of A. Gregory Sorensen, and Sarah F. Kulke)

with high magnetic susceptibility. Six SE echo planar images ($TR = 1$ s, $TE = 100$ ms) from the series (11, 14, 17, 20, 25 and 31 s post-injection) are shown in Figure 3(a), and reflect the parenchymal signal attenuation during transit of agent. Figure 3(b) shows the complete time course from a cortical region of interest.

4.2 Applications

Dynamic first-pass contrast agent studies using Gd-DTPA¹² and Dy-DTPA have produced relative cerebral blood volume (CBV) maps. From tracer kinetic theory,¹³ the area under the tissue concentration–time curve for a purely intravascular tracer is proportional to local blood volume. In the presence of an intact blood–brain barrier, Gd-DTPA and Dy-DTPA remain intravascular during cerebral passage, and the associated relaxivity–time curve for each pixel can be numerically integrated to yield a map proportional to CBV.¹⁴ Such maps have been used for understanding fundamental questions of neuroscience, assessing cerebrovascular accident, and also for improving diagnostic sensitivity and specificity in various neuropathologies, as they appear closely correlated to tumor grade, match PET ¹⁸F-DG maps in a majority of cases studied, and may differentiate recurrent tumor from radiation necrosis.^{12,15} Exogenous susceptibility-contrast studies have also been proven to be sensitive to local changes in CBV concomitant with increased neuronal activity, and have been used to map the visual cortex.¹⁶ Endogenous susceptibility contrast, sensitive to neuronal activity-induced changes in both CBV and hemoglobin oxygenation, is currently being used at several sites to map changes in cerebral neuronal activity associated with task activation.^{17–21}

Measurement of hemodynamic parameters with dynamic susceptibility-contrast MRI²² necessitates understanding the mechanisms of susceptibility-induced contrast, and knowledge of the relationships between relaxivity change and compartment size, agent concentration, and vascular volume fraction.

4.3 Size Dependence

Phantom studies with polystyrene microspheres suspended in contrast agent have demonstrated convergence between Monte Carlo models and experiment for spherical magnetic field perturbers.⁹ Figure 4 plots ΔR_2 versus sphere size with 3.2 and 9.6 mM Dy-DTPA for both empirical (solid symbols) and Monte Carlo (open symbols) measurements. These results demonstrate the strong compartment size dependence for SE images.

Cylindrical Monte Carlo models more accurately represent contrast agent within the vasculature¹¹ and have elucidated features of in vivo contrast. Figure 5 depicts the GE ($TE = 60$ ms) and SE ($TE = 100$ ms) vessel size-dependence of relaxivity change for $f_v = 2\%$ and $\Delta\chi = 1 \times 10^{-7}$ (cgs units; equivalent to ≈ 3.6 mM Gd-DTPA,²³ a typical first-pass concentration for a 0.1 mmol kg^{-1} injection). Whereas SE relaxivity peaks for microvessels, GE relaxivity exceeds SE relaxivity at all radii and reaches a plateau for macrovessels.

This selective sensitivity to microvessels for SE contrast comes from the balance between two competing effects. For large enough compartments, protons diffuse a short distance compared with the compartment radius and can be considered

Figure 4 Size dependence of susceptibility-induced relaxation for two values of $\Delta\chi$. For both concentrations, SE relaxivity peaks between $R = 2$ and $5 \mu\text{m}$. To the left of this peak, motional averaging reduces ΔR_2 ; to the right of this peak, the size of the gradient decreases with increasing particle size. Increasing concentration (increasing $\Delta\chi$) shifts the curves up and to the left. By tripling the concentration, we approximately triple the peak relaxation, and shift the curve over by approximately $\sqrt{3}$ in radius. The filled symbols are experimental data points, the open symbols are Monte Carlo data points. The error bars for the Monte Carlo simulations are smaller than the plot symbols. (Experimental data courtesy of Chun S. Zuo)

to diffuse in a constant, though spatially varying, gradient that is inversely proportional to the compartment size. Because relaxation is a function of the square of the gradient, relaxivity diminishes dramatically with increasing compartment size. For small compartments, each proton accumulates little phase as it diffuses by a compartment, since phase accumulation is proportional to the time required to diffuse past a perturber, $\tau \sim$

Figure 5 Size dependence of GE ($TE = 60$ ms) and SE ($TE = 100$ ms) relaxivity change for $f_v = 2\%$ and $\Delta\chi = 1 \times 10^{-7}$. At this $\Delta\chi$, SE relaxivity peaks for microvessels. GE relaxivity exceeds SE relaxivity at all radii, reaches a plateau for macrovessels, and is actually greater for macrovessels than for microvessels

Figure 6 Relative CBV maps obtained with dynamic susceptibility-contrast bolus tracking. (A) GE acquisition, with $TE = 60$ ms, $TR = 1500$ ms, and dose = 0.1 mmol kg^{-1} . (B) SE acquisition, with $TE = 100$ ms, $TR = 1500$ ms, and dose = 0.2 mmol kg^{-1} . The TE and dose were chosen to produce approximately equal signal drops. The GE map is dominated by large vascular structures: note the macrovascular prevalence along the convexity and falx. By comparison, the SE map exhibits superior gray-white tissue discrimination and definition of central structures due in part to superior tissue-level microvascular sensitivity. (Images acquired by Hannu Aronen)

r^2/D . The diffusion of each proton averages the effect of many perturbers, effectively narrowing the broad distribution of frequencies and reducing relaxivity.

Spin echo acquisitions are therefore selectively sensitive to microvascular contrast and are capable of reflecting true tissue level blood volume, whereas GE acquisitions reflect total vascular blood volume because all vessels contribute approximately equally to GE contrast. However, because SE acquisitions have significantly less signal attenuation than GE acquisitions, a tradeoff exists between overall sensitivity and microvascular specificity. The ability of MR to be selectively sensitive to microvascular contrast is unique among tomographic modalities, and constitutes the appeal of MR for assessing true blood volume at the microvascular level. Radionuclide contrast, by comparison, is directly proportional to the amount of tracer in vessels of all sizes, and can therefore only reflect total blood volume.

The clinical implications of the size-dependence relationships are exemplified in Figure 6, which depicts a GE [Figure 6(A); $TE = 60$ ms, dose = 0.1 mmol kg^{-1}] and an SE [Figure 6(B); $TE = 100$ ms, dose = 0.2 mmol kg^{-1}] relative CBV map from dynamic bolus tracking of Gd-DTPA with $TR = 1500$ ms. The TE and dose were chosen to produce approximately equal peak signal drops. The GE map is dominated by large vascular structures, including macrovascular prevalence along the convexity and falx. By comparison, the SE map exhibits superior gray-white tissue discrimination and definition of central structures due to superior tissue level microvascular sensitivity.

4.4 Concentration Dependence

The concentration dependence of relaxivity change has been determined through simulation and experiment to be generally linear for typical first-pass concentrations of contrast agent.

Figure 7 Comparison of GE and SE ($TE = 20$ ms) Monte Carlo ($f_v = 1.5\%$ composed of 0.75% $r = 3 \mu\text{m}$ vessels and 0.75% $r = 25 \mu\text{m}$ vessels) and experimental ($f_v = 1.54 \pm 0.78\%$, $n = 5$ rats) relaxivity change for one rat as a function of vascular concentration of AMI-227 at 4.7 T. (Experimental data courtesy of Leena M. Hamberg)

Figure 7 demonstrates relatively linear behavior between cumulative doses of AMI-227 [with a long intravascular half-life and a measured $\Delta\chi$ in blood of $3.4 \times 10^{-7} \text{ mM}^{-1}$ (cgs) at 1.5 T²²] and measured GE and SE relaxation in Wistar rat brain at 4.7 T. Contrast agent concentration in the blood was determined by assuming total retention of contrast agent during the experiment and complete, uniform mixing of agent in a total blood volume of 6 mL per 100 g of total body weight.²⁴ Also shown in Figure 7 is the Monte Carlo concentration dependence for $f_v = 1.5\%$ (the average whole-brain CBV for $n = 5$ rats determined by a radiolabeled albumin technique) equally distributed between capillaries ($R = 3 \mu\text{m}$) and venules ($R = 25 \mu\text{m}$). The model also predicts a linear concentration dependence and agrees well with experiment for this volume fraction.

4.5 Volume Fraction Dependence

The application of tracer kinetic theory to relaxivity-time data requires that relaxivity be proportional to f_v .²⁵ This dependence is difficult to assess in vivo, but can be predicted with numerical techniques. In Figure 8, the Monte Carlo model was used to plot the ratio of GE [Figure 8(a); $TE = 60$ ms] and SE [Figure 8(b); $TE = 100$ ms] relaxivity change for $f_v = 2\text{--}6\%$ to that for $f_v = 1\%$ at $\Delta\chi = 1 \times 10^{-7}$. The results demonstrate that for all vessel sizes, relaxivity scales proportionally with volume fraction. A linear relationship over a physiologically relevant range of vascular volume fraction is therefore predicted for a vasculature composed of any combination of vessel sizes.

5 SUMMARY

This article summarizes the susceptibility-contrast physics that underlies the artifacts and applications of susceptibility-based NMR image contrast. Macroscopic susceptibility effects create artifacts associated with poor shimming, metallic implants, and susceptibility differences at air-tissue interfaces.

Microscopic effects can be exploited by dynamic imaging with and without contrast agents to impact profoundly the quantification of important physiological parameters like blood flow, volume, and oxygenation under a wide range of physiologic and pathophysiologic conditions.

Tissue Water and Lipids: Chemical Shift Imaging and Other Methods

W. Thomas Dixon

Emory University, Atlanta, GA, USA

1 INTRODUCTION

Most signal contributing to images *in vivo* comes from water and from lipid methylene protons which resonate at a frequency about 3.4 ppm lower. Other spins are so much rarer they are not seen without special effort. Spectroscopic imaging sensitive to these additional, minor lines as well is discussed in *Chemical Shift Imaging*. Because more measurements are required to determine more unknowns, imaging methods that can determine pixel intensities at the chemical shifts of many rarer resonances are slower or provide coarser spatial resolution than those dealing with only a two-line spectrum. Methods described in this article typically produce images with the same spatial resolution as standard, chemical shift blind imaging methods. Because images are made from echoes, only water and lipid lines with reasonable T_2 values contribute. Lipid droplets are readily seen but membrane lipids are not. The contribution of intracellular water to most images has been questioned.¹ This article explains why and how this basic, two-line spectrum is manipulated in imaging. The subject has been reviewed more thoroughly before.^{2,3}

2 MANIPULATION TYPES AND USES

What water and lipid manipulations are desired and why? When lipids are a nuisance in images, fat suppression is

needed; when lipid is to be studied, water suppression may be useful; when fat/water interfaces, displacement of water by fat or of fat by water are to be detected, an image of water signal minus lipid signal is very sensitive.

2.1 Lipid Suppressed Images

Lipids signals are often a nuisance. Because lipid is abundant, has high proton density, and repolarizes before the water in most tissues, it is the dominant source of signal in many images. A small fraction of the lipid signal in the wrong place often degrades images of less intense but medically important, watery regions. Optic nerves are surrounded by fat and provide an example of the benefit of suppressing fat. Signal increases in the spinal chord, brain, optic nerves, and retinas following injection of Gd-DTPA are a sign of pathology. Ordinarily, a barrier around blood vessels in these organs prevents Gd-DTPA and many other substances from escaping into the surrounding tissue. However, when this barrier is damaged, Gd in the tissue enhances longitudinal relaxation and therefore increases signal intensity. The patient shown in Figure 1 has autoimmune optic neuritis affecting the right side with an apparently normal left side. The increased intensity of the right optic nerve, relative to the left side or to the brain, is easily seen when fat is suppressed, but not when the nerve is surrounded by high intensity fat.

Fat signal gets out of control in several ways. The most important are probably spreading of the lipid signal in the phase-encoding direction when fat moves (heart beat, breathing, wiggling), Gibbs's ringing, and the 'chemical shift artifact'. This artifact is an offset in apparent position of lipid in the slice selection and read gradient directions caused by the water-lipid chemical shift difference. Gibbs's ringing and the chemical shift artifact obscure small structures near a large amount of fat. Cartilage in joints and the optic nerve are examples. Moving fat produces long-range phase-encoding artifacts which are a serious problem in the abdomen and thorax. These can, for example, interfere with the detection of low contrast masses in the liver. Side lobes or other slice selection problems, quadrature errors, lack of dynamic range in signal detection, instrument instability, and coil tuning variations caused by

Figure 1 T_1 -Weighted images of the optic nerves. The right optic nerve (arrow, left side of image), but not the left optic nerve, is enhanced in intensity by Gd-DTPA. Saturation of the surrounding fat by a selective pulse made this easier to detect in the image at right. (Courtesy of Dr. Susan B. Peterman)

breathing can also spread lipid signal to lipid-free regions of an image.

Fat suppression methods are not perfect. Generally, partial water suppression is a more serious image flaw than is incomplete or nonuniform fat suppression; however, both flaws may be serious in quantitative imaging. Examples of quantitative studies in organs which accumulate lipid are measuring the fat content of the heart⁴ or the water relaxation rates of the liver.⁵ Water relaxation measurements may be distorted by partial water suppression and will be by any lipid signal, whether it originates within the region of study or elsewhere.

2.2 Water Suppressed Images

Most methods suitable for fat suppression can suppress water instead, and some easily produce an image pair, one of fat, the other of water. Replacement of cancer by fat is a favorable prognostic indicator. Lipid signal from heart muscle may indicate myocardial ischemia or infarction.⁴ For some nutritional studies, quantitation of adipose tissue is needed. Water suppression is useful here.

2.3 Opposed Images

Lipid images by themselves can be hard to interpret because interesting organs and landmarks for finding them are lipid-free and invisible. However, the presence of fat can be a useful source of contrast or mark the distinction between muscles or other organs. Images in which the phase of the fat signal is opposite to that of the water, 'opposed images', have the chemical shift information of a lipid image but show all anatomic structures. These images can be made on purpose, and in gradient echo imaging occur incidentally when certain echo times are chosen. Usually images are presented as absolute values. At fat/water interfaces in absolute value opposed images, a line of dark pixels occurs where the water and fat signals within the pixels cancel. A dark outline can make it easy to see a lymph node or an adrenal gland surrounded by fat of similar intensity. Of course, if the absolute value is not taken, or rather the effort is made to preserve the sign, all organs are easily distinguished from fat.

Liver can be diffusely infiltrated by fat. Opposed images are more sensitive to infiltration than water-suppressed or fat-suppressed images because they show both the increase in fat signal and decrease in water signal caused by displacement. Decreasing liver intensity this way can aid detection of metastases in liver⁶ because the intensity of the metastases is not affected.

Some applications simply require any manipulation that identifies lipids. For example, in leukemia, fatty bone marrow in the spine is replaced by water but reappears after successful treatment.⁷

3 METHODS

The following outline orders some of the many published fat–water manipulation methods by principle of operation.

Many pulse sequences combining different methods of operation have been demonstrated also.

Longitudinal relaxation (Section 3.1):

Single inversion (STIR)

Double inversion

J Coupling (Section 3.2):

Classical multiple quantum sequences

Multiple echo fast imaging sequences

Chemical shift (Section 3.3):

Selective rf pulses

– rf pulses without gradients (selective excitation; selective suppression)

– rf pulses with gradients

Phase methods

– Hahn and gradient–echoes

– gradient–echoes only

3.1 T_1 Based Fat Suppression

The T_1 -based, short inversion time inversion–recovery, STIR,⁸ is a very simple fat suppression method. An inversion–recovery image is made with TI chosen to null signal from undesired fat. With a long TR , this is $(\ln 2)T_1$. With proper interleaving of pulses, multislice IR imaging can be quite time efficient.

Because this method is not sensitive to shimming and is hardly sensitive to flip angle variations, it can give uniform suppression over a large region. Adipose tissue contains some water and varies regionally in composition. Temperature and relaxation rates also vary, especially in the skin; therefore, suppression is not completely uniform. Either the lipid signal or the combined lipid and water signal from adipose tissue can be nulled with the proper TI ; the difference is slight.

Objections to STIR for fat suppression are that it partially suppresses water, by a different amount in different tissues, and it fixes TI so that T_1 -weighting cannot be effectively adjusted. Figure 2 illustrates this for a typical STIR sequence. Assuming relaxation rates for fat and most other tissues are around 4 s^{-1} and 1 s^{-1} , respectively, this sequence gives

Figure 2 Intensity and T_1 -weighting in STIR images. Signal intensity (bold line) and T_1 -weighting (fine line) versus longitudinal relaxation rate. Weighting is defined here as 100-times the intensity change caused by a 1% rate change. Weighting and intensity are measured in units of equilibrium magnetization. (Pulse sequence $TR/TI/TE = 2500/175/\text{negligible ms}$)

essentially no T_1 -weighting for most tissues and most tissue magnetizations are just over one-half their equilibrium values.

Following a second inversion pulse, tissues with two different T_1 values can recover to zero magnetization simultaneously. Two inversion times must be adjusted to align the two zero crossings. In angiograms, pictures of flowing blood, this has been done⁹ to eliminate both fat and one other tissue (muscle or brain) from images.

3.2 J Coupling

Lipids have J -coupled spins while water does not. Classic multiple quantum pulse sequences have been combined with imaging to produce lipid images.¹⁰ More recently, J coupling has been proposed as an important reason that fat is more intense in certain fast images than in conventional images having the same nominal TE . These fast images (RARE) collect several lines of k -space in closely spaced Hahn echoes following each excitation [*Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI*]. J coupling reduces the intensity of coupled spins less when more 180° pulses are used to produce an echo at a given time. This has led to the production of lipid images by subtracting fast images made with the same echo time but different numbers of refocusing pulses.¹¹ Water intensity is much less dependent on the number of refocusing pulses used. A threshold can be set to identify voxels containing fat, and postprocessing then used to produce either water or lipid images.¹¹

J coupling methods are immune to shimming problems and are temperature-independent. They require that two images be made to obtain any chemical shift information. This takes additional time and increases sensitivity to motion, even if acquisitions of the two images are interleaved. Water images will necessarily be T_2 -weighted and lipid images will have an intensity which may depend in a complicated way on lipid chemistry.

3.3 Chemical Shift Based Methods

For most of our concerns, the spectrum of tissues can be approximated as two δ functions 3.4 ppm apart. An approximation that cannot be made is that the water Larmor frequency is everywhere the same. Shimming is by far the most serious problem with chemical shift based lipid manipulation schemes. Even if the magnet is perfectly shimmed when empty, the susceptibility of the subject distorts the field by an amount comparable to the 3.4 ppm separation between fat and water resonances. To aid shimming, the subject can be surrounded by a material with a susceptibility near that of water, but near cavities such as sinuses, airways, lungs, or bowel gas, this does not help.

3.3.1 Chemically Selective rf Pulses without Gradients

A simple approach to chemical shift imaging is to saturate either the water or the fat magnetization before a standard imaging sequence.¹² This can be done with a soft, frequency selective pulse of about 90° in the absence of a gradient, followed by a spoiling gradient, then the rest of the imaging sequence. As an alternative to the extra chemical shift selective pulse, one of the pulses in a multipulse imaging sequence can

be made chemically rather than spatially selective. A chemical shift selective saturation pulse can be applied during an inversion-recovery sequence at the time of the zero crossing of fat. This combined method has been compared with some other chemically selective pulse methods.¹³ Of these shift selective pulse methods, those with pulses selective for the desired signal are harder to incorporate in multislice methods than those selectively exciting the unwanted species.

In the presence of shimming errors, an rf pulse intended to suppress fat may suppress water instead in regions with a lower field and suppress nothing at all in higher field regions. Such pulses can give good results in relatively small regions that are not near odd-shaped air spaces and which can be placed at the magnet isocenter, for example the knee. A suppression pulse combined with surface coil reception is useful in examining the spine. The surface coil's lack of sensitivity to moving fat in the front of the body prevents phase-encoding artifacts, so the suppression pulse need only be effective near the spine. Magnet shimming is in general much better now than when selective pulse methods were put forward. Originally only of academic interest, selective pulses are now included in commercial, clinical software for fat saturation.

3.3.2 rf Pulses with Gradients

Angiograms, or images of flowing blood, can be made from a stack of thin, highly T_1 -weighted images. Most tissues are dark because there is little time for recovery between acquisitions. Blood flows into the slice fully polarized if it moves more than a slice thickness in TR . Fat limits the smallest vessels that can be seen because it recovers magnetization rapidly and has an intensity comparable to the blood in small vessels. Veins present another problem in images of arteries. Veins usually run along arteries but are less often of interest. Both problems can be solved simultaneously by saturating a thick slab on one side of the slice being imaged.¹⁴ This is done using a soft pulse with a weak gradient. The slab is positioned to saturate venous blood upstream of the slice but arterial blood downstream, thus removing veins but not arteries from the angiogram. The region of fat saturated by the extra pulse is not exactly the same as the region of water saturated because of the Larmor frequency difference. The gradient direction and magnitude for saturating the slab are chosen so that fat in the region to be imaged is saturated, but upstream blood is not. The shimming effect on this fat suppression method depends on the gradient strength. Excited slices are not perfectly flat but are warped like potato chips. Consecutive slices will nest perfectly if made with the same gradient and the same rf pulse (except for a frequency shift) but otherwise will overlap or leave gaps where none are intended.

3.3.3 Phase Based Methods

These methods are based on the difference between a gradient echo and Hahn's original spin echo, better called a Hahn, rf recalled, or rf echo to avoid confusion (Figure 3). Pixel phase in the image is the spin phase at the time of the gradient echo. At a Hahn echo, spin phase is independent of chemical shift and shimming. Therefore, when these echoes coincide, water and fat have the same phase in the reconstructed image.

Figure 3 Hahn and gradient echoes in a spin echo imaging sequence

When they do not, phase accumulates at the Larmor frequency from the Hahn echo until the gradient echo. (For simplicity, the model uses a frame rotating at the instrument frequency.) Because the water-fat Larmor frequency difference is known, images with any desired phase difference between lipid and water can be produced by choosing the two echo times carefully.

Availability of starting images with known water-lipid phase shifts creates an urge to Fourier transform them for presentation. Transforms with one,¹⁵ two,^{16,17} three,¹⁸ four,¹⁹ and more²⁰ starting images have been used. Using more starting images allows the solution of more equations (by FT) for more unknowns. Formally, the output of a one-point FT is the same as its input. This is appropriate for opposed images as discussed before. The output of a two-point FT is the sum and the difference of the input points. Given images with water and lipid in phase and 180° opposed, a two-point FT produces separate, quantifiable images of lipid and of water. Additional unknowns of interest that can be imaged by phase-based methods include regional B_0 variation and the lipid linewidth.

Phase-based manipulations are most straightforward when refocusing pulses produce Hahn echoes. This allows images with different phase relations to be made with the same gradient echo time. In these, regions differ because of chemical shift differences but not because of T_2 differences. Nevertheless, phase-based fat suppression has been done with gradient echoes alone in the absence of refocusing pulses.²¹

The sign of a signal is often a question in IR imaging, especially when contrast agents are employed. In images produced by phase-based fat-water manipulations, the sign is always a question and occasionally a problem. If the phases and the signs of signals were ideal, separation of fat (F) from water (W) images given in phase (Si) and opposed (So) images would be unambiguous.

$$\left. \begin{array}{l} \text{Si} = \text{W} + \text{F} \\ \text{So} = \text{W} - \text{F} \end{array} \right\} \rightarrow \left. \begin{array}{l} 2\text{W} = \text{Si} + \text{So} \\ 2\text{F} = \text{Si} - \text{So} \end{array} \right\} \quad (1)$$

However, if only absolute value images are available,

$$\left. \begin{array}{l} 2\text{W} = |\text{Si}| + |\text{So}| \\ 2\text{F} = |\text{Si}| - |\text{So}| \end{array} \right\} \text{ or } \left. \begin{array}{l} 2\text{F} = |\text{Si}| + |\text{So}| \\ 2\text{W} = |\text{Si}| - |\text{So}| \end{array} \right\} \quad (2)$$

The second solution applies where $\text{F} > \text{W}$. Simple-minded addition of images to produce a water image and subtraction to produce lipid images incorrectly reports a 60:40 mixture of lipid and water signal as 40:60 and so forth. The impact of this twofold ambiguity varies. Adipose tissue appears in the water instead of in the lipid image. Quantitative studies of fatty livers are affected while searches for liver metastases are not. Whenever the absolute value reverses the sign of the opposed image, misclassification occurs.

In principle, use of the original, complex images rather than absolute value images prevents the twofold ambiguity in fat signal fractions. In practice, images made with gradient and Hahn echoes which do not coincide have complicated phases depending on things other than chemical shift, shimming being the most important. The sign problem has been solved by noting that chemical shift often changes suddenly from one voxel to the next but B_0 always changes gradually. In a phase map, fat/water boundaries can produce buttes or mesas superimposed on slowly rolling hills produced by shimming or other instrumental errors. A global view allows identification of region boundaries and therefore correction of signs in absolute value and absolute value-derived images. This phase unwrapping shows that one region is primarily lipid and another primarily water, but another method, usually inspection, is needed to show which is which.

When the phase of a particular pixel corresponds to a frequency 3.4 ppm off reference, that could indicate its signal comes from lipid rather than water. Alternatively B_0 could be 3.4 ppm low at that location. No local method using information from that voxel alone can distinguish chemical shift differences from B_0 differences, regardless of what pulse sequence is used or how many basis images are available. Even though the fat signal fraction ambiguity can only be solved by improved reconstruction methods, not by improved pulse sequences, desire to solve this ambiguity has led to new pulse sequences. Pulse sequence changes can make phase unwrapping easier. For example, increasing the phase difference between water and lipid from 180° to 360° removes the chemical shift induced cliffs from the opposed image phase map while doubling the height of the pattern of rolling hills caused by shimming and other variables.^{19,22} The resulting B_0 map helps unwrap the opposed image and can be used to adjust the instrument. Using comparison images of a phantom with uniform chemical shift also helps solve the sign problem.²³

A less elaborate solution has been used to determine fat fractions in large regions of interest in vertebral bone marrow of leukemia patients.⁷ Examination of the real opposed image determines whether signals from the marrow and from the intervertebral disks have the same or opposite signs. The disks contain no fat and have a positive signal. Knowing the sign of the opposed image signal removes the twofold ambiguity in fat signal fraction.

4 OTHER USES

Manipulations described here can be used for substances other than fat. T_1 -Based fat suppression has been combined with frequency selective water suppression pulses^{24,25} to image silicone prostheses. Silicone images have also been produced using opposed images in which delays were chosen to produce water/lipid, methylene/silicone, methyl proton phases of 0°, 0°, 180°.²⁶ Fluorinated blood substitutes are difficult to image because multiple resonances with large shift differences frustrate position determination in both slice selection and read directions. Pulse sequence²⁷ and reconstruction changes^{28,29} can help. Imaging the sugar distribution in grapes³⁰⁻³² is a challenging application because glucose and fructose spectral lines lie closer to water than do lipid lines.

Whole Body Studies Involving Spin–Lattice Relaxation in the Rotating Frame

Raimo E. Sepponen

Helsinki University of Technology, Helsinki, Finland

1 INTRODUCTION

The dependence of the longitudinal relaxation time T_1 of biological tissue on the strength of the polarizing magnetic field B_0 , i.e., on the NMR frequency ν_0 is often called T_1 dispersion.¹ The efficiency and the number of relaxation mechanisms related to water–macromolecule interaction increase with decreasing ν_0 , and tissue T_1 s get shorter. Longitudinal relaxation observed at low field strengths may therefore discriminate better between normal and pathological tissues than that observed at high field strengths. The spin lock (SL) technique allows studies of relaxation at very low field strengths with a high signal-to-noise ratio.

In an SL experiment, nuclear spins are locked with a radio-frequency (rf) field. The locked nuclear magnetization relaxes along the magnetic component of the locking rf field, B_{1L}' ,

which rotates at an angular velocity ω_1 . If the frequency ν_1 of the rf field is equal to ν_0 , the relaxation is characterized by the relaxation time $T_{1\rho}$, which is approximately T_1 at B_{1L} . If ν_1 differs from ν_0 then the relaxation time is called $T_{1\rho}^{\text{off}}$, which approaches T_1 as the frequency offset increases; generally $T_2 < T_{1\rho} < T_{1\rho}^{\text{off}} < T_1$.² At very low strengths of B_{1L}' , $T_{1\rho}$, $T_{1\rho}^{\text{off}} \approx T_2$. The strength of B_{1L}' may be varied by variation of the strength and/or frequency of the rf field. Hence, the SL technique allows studies of dispersion of relaxation in the rotating frame, i.e., $T_{1\rho}$ dispersion.

The relative efficiencies of different relaxation mechanisms under the locking conditions are still to be evaluated. It has been assumed that thermal motion of macromolecules and slow motions of water molecules such as chemical exchange are important sources of relaxation. However, it has been suggested that relaxation under the locking conditions is mainly a manifestation of magnetization transfer (MT) between mobile water protons and solid state broadened protein proton levels.^{3–5}

The potential to provide unique relaxation information and tissue contrast has motivated the development of clinically feasible SL imaging techniques.^{6,7}

2 SPIN LOCK IMAGING TECHNIQUES

In an SL experiment, the longitudinal nuclear magnetization M_z is tilted from the direction of the polarizing magnetic field B_0 by an rf pulse or an adiabatic sweep. This is followed by a locking pulse, B_{1L}' , which is applied during the locking time TL . This is illustrated in Figure 1, which shows the basic SL imaging sequence.⁸ The phase of B_{1L}' is adjusted so that the

Figure 1 The basic pulse sequence for $T_{1\rho}$ imaging. TR is the repetition time, B_{1L}' is the locking radio frequency pulse applied at ν_0 , TL is the length of the locking pulse, and TE is the time to echo: 'rf' indicates radiofrequency operations; 'Slice select' indicates slice-selection gradient operations; 'Phase encoding' indicates phase-encoding gradient operations; 'Read' indicates read gradient operations, and 'Signal' indicates NMR signals

magnetic component of the effective field is aligned with the tilted $\mathbf{M}$. The locked magnetization relaxes along $\mathbf{B}_{1L}'$ with a characteristic relaxation time $T_{1\rho}$ or $T_{1\rho}^{\text{off}}$.

In imaging applications of the SL technique, $\mathbf{B}_{1L}'$ is followed by an excitation, gradient encoding, and signal collecting sequence (Figure 1).

The intensity S of the signal is given approximately by

$$S \propto M_0(1 - e^{-TR/T_1}) e^{-TE/T_2} e^{-TL/T_{1\rho}} \quad (1)$$

Generally, tissues with a long T_2 also have a long $T_{1\rho}$, so the inevitable T_2 weighting of the final image does not decrease the contrast. This allows optimization of the signal-to-noise ratio by selecting TE . TR should be relatively long in order to minimize the antagonistic T_1 weighting.

If the strength of $\mathbf{B}_{1L}'$ is low, the contrast properties of $T_{1\rho}$ -weighted images are similar to those of T_2 -weighted images.⁹ An increase in the strength of $\mathbf{B}_{1L}'$ makes the $T_{1\rho}$ of tissues longer and alters the contrast.⁸

$T_{1\rho}$ dispersion may be quantified by collecting two or more SL images with different $\mathbf{B}_{1L}'$ strengths. This unique information about relaxation processes may prove useful in tissue characterization.

For calculated $T_{1\rho}$ images, at least two images with different TL values need to be collected. The calculation is similar to the calculation of a T_2 image.

A multiple slice SL imaging technique has been recently introduced.¹⁰ The multiple slice SL imaging sequence is presented in Figure 2. Nonselective, short locking pulses are used for the generation of the $T_{1\rho}$ contrast in the whole imaging volume. After each locking pulse, the magnetization is returned to the direction of $\mathbf{B}_0$. In this way, the generated contrast is 'stored' in the longitudinal magnetization. The images are obtained with the multiple slice technique.

The intensity S of the signal is given by

$$S \propto M_0 \sin \theta \frac{E_2[1 - (E_D E_L)^N](1 - E_D)E_L}{[1 - (E_D E_L)^N \cos \theta](1 - E_D E_L)} \quad (2)$$

where

$$E_2 = e^{-TE/T_2}, \quad E_D = e^{-TD/T_1}, \quad E_L = e^{-TL/T_{1\rho}} \quad (3)$$

The contrast also depends on the number N of slices and the time delay TD between successive locking pulses. A small θ generally has a synergistic effect on the contrast by reducing the antagonistic T_1 weighting.

With this sequence, high-contrast images may be obtained by using a short TE . This minimizes motion artifacts and allows a large number of slices to be accommodated within a given TR . This makes the sequence feasible for abdominal imaging, for example. TL may be short, because of the cumulative effect of the locking pulses. TD should be short compared with T_1 s of tissues.

3 RESULTS WITH T_1 AND $T_{1\rho}$ DISPERSION IMAGING

$T_{1\rho}$ imaging may prove to have a good capability for tissue differentiation. For example, $T_{1\rho}$ measured at $B_{1L} = 0.23$ mT discriminated tumor from normal fat and fibrous breast tissues. Conventional T_2 and T_1 measurements at $B_0 = 0.15$ T failed to demonstrate this difference.¹¹

$T_{1\rho}$ dispersion imaging has been used to evaluate brain and muscle diseases. Fresh brain infarctions and plaques of multiple sclerosis have a long $T_{1\rho}$ and a slightly smaller $T_{1\rho}$ dispersion than normal brain tissue in the B_{1L} range 0.05–0.46 mT.⁷

A difference in $T_{1\rho}$ dispersion has been found between normal and diseased muscle tissue. The B_{1L} range used was 0.025–0.25 mT. The method seems to provide better identification of affected muscles than T_1 - and T_2 -weighted imaging.¹²

Figure 2 The multiple slice SL sequence. The notation is the same as in Figure 1; θ indicates a θ° excitation pulse

Figure 3 (a) A multiple slice SL image of a female pelvis. The imaging parameters are $TR = 1500$ ms, $TE = 40$ ms, $B_{1L} = 60 \mu\text{T}$, $TL = 10$ ms, $\theta = 60^\circ$, and $B_0 = 0.1$ T. The gradient echo technique has been used. A cyst is visible adjacent to the urinary bladder, with a high signal intensity. The wall between the urinary bladder and the cyst is also visible. (b) A gradient echo (GE) image of the same slice as in (a). The imaging parameters are $TR = 1500$ ms, $TE = 40$ ms, $\theta = 60^\circ$, and $B_0 = 0.1$ T. Note that the intensity of the adjacent intestine is as high as that of the cyst. The contrast between muscle and fat tissues is better in the SL image than in the GE image

$T_{1\rho}$ dispersion imaging has been shown to be highly sensitive to the presence of paramagnetic substances. This has been demonstrated in a mouse tumor. $T_{1\rho}$ dispersion imaging seems to be superior to conventional T_1 -weighted imaging in detecting the presence of a paramagnetic contrast agent.¹³

The SL technique may be used with the inversion-recovery method to improve the conspicuity of blood vessels in angiography. The length of the locking pulse and the inversion time may be adjusted in order simultaneously to suppress, for example, fat and muscle signals.¹⁴ SL contrast between blood and cardiac muscle has been exploited in cardiac imaging at 1.5 T.¹⁵

The SL technique seems to provide a sensitive method to detect fluid collections, such as edema and cysts in different body areas. This is demonstrated in Figures 3 and 4. In Figure 3, a cyst adjacent to the urinary bladder is differentiated better in the SL 1500/30 ($B_{1L} = 60 \mu\text{T}$, $TL = 10$ ms, $\theta = 60^\circ$, $N = 15$, $B_0 = 0.1$ T) image (a) from intestines than in a gradient echo GE 1500/30 image (b). Note that the contrast between subcutaneous fat and muscle tissue is better in the SL image than in the conventional GE image.

In Figure 4, fluid collections in an injured knee are better discriminated in the SL 1500/40 ($B_{1L} = 50 \mu\text{T}$, $TL = 8$ ms, $\theta = 60^\circ$, $N = 12$, $B_0 = 0.1$ T) image (a) than in the GE 1500/40 image (b). Note the high contrast between fluid and cartilage tissue in the SL image.

As already mentioned, the SL technique may provide complementary information for tissue characterization to the conventional imaging methods. In Figure 5, the visualization of a multiple sclerosis plaque is demonstrated with the multiple slice SL technique (a) and with the conventional T_2 -weighted spin echo (SE) technique (b). In the SL 1500/45 ($B_{1L} = 60 \mu\text{T}$, $TL = 10$ ms, $\theta = 60^\circ$, $N = 12$, $B_0 = 0.1$ T) image, the center of

the lesion has a relatively low intensity. This feature is difficult to appreciate in the SE 2100/120 image. $T_{1\rho}$ imaging has been successfully used for perfusion imaging of brain. An introduction of ^{17}O enriched water in blood increases $T_{1\rho}$ dispersion of perfused tissue.¹⁶

Because the contrast in SL images is closely related to the contrast obtained with the MT technique, the potential of SL imaging has been studied in areas of the body where MT contrast has been explored. It has been demonstrated that SL imaging provides an effective method for detection of pathologies in the head and neck area.¹⁷ Detection and differentiation of liver tumors is one application for SL imaging.¹⁸

SL contrast is generated when the spins are locked and, therefore, short TE may be employed. Hence, SL technique may be used in areas such as lungs where susceptibility artifacts are significant and the use of conventional spin echo technique with long TE is not feasible.

4 INSTRUMENTATION AND SAFETY

The instrumentation required for spin lock experiments is usually available in a standard MRI unit. However, the rf power amplifier for supplying the long, high-amplitude B_{1L}' pulse may be limited to ensure rf safety. The excitation and B_{1L}' pulses are emitted by the same coil system, which should be able to withstand the required rf power.

The rf absorption of biological tissues is described by the specific absorption rate (SAR). This is proportional to the product $(B_{1L}')^2 B_0^2 TL/TR$. The duty cycle TL/TR and amplitude of B_{1L}' at B_0 are limited by the maximum allowed SAR.⁷

Figure 4 (a) A multiple slice SL image of an injured knee. The imaging parameters are $TR = 1500$ ms, $TE = 40$ ms, $B_{1L} = 50 \mu\text{T}$, $TL = 8$ ms, $\theta = 60^\circ$, and $B_0 = 0.1$ T. The gradient echo technique has been used. A small fluid collection adjacent to the patellar cartilage is clearly visible, with a high signal intensity. Muscle tissue shows a very low signal intensity. (b) A gradient echo (GE) image of the same slice as in (a). The imaging parameters are $TR = 1500$ ms, $TE = 40$ ms, $\theta = 60^\circ$, and $B_0 = 0.1$ T. Note that the contrast between the fluid collection and the patellar cartilage is low. Muscle tissue has a markedly higher signal intensity than in the SL image

The SL technique can be applied at medium and high fields by locking the magnetization with an off-resonance rf pulse B_{1L}^{off} and by using the multiple slice SL technique. The SAR in

the multiple slice SL images presented earlier is less than 0.12 W kg^{-1} . This indicates that the technique may be safely used at any field strengths currently in clinical use.

Figure 5 (a) A multiple slice SL image of a patient suffering from multiple sclerosis. A multiple sclerosis plaque is visible, with a high signal intensity. The center of the lesion has a slightly lower intensity. The imaging parameters are $TR = 1500$ ms, $TE = 45$ ms, $B_{1L} = 60 \mu\text{T}$, $TL = 10$ ms, $\theta = 60^\circ$, and $B_0 = 0.1$ T. (b) A T_2 -weighted SE 2100/120 image of the same slice as in (a). The lesion has a high signal intensity. The imaging parameters are $TR = 2100$ ms, $TE = 120$ ms, $\theta = 90^\circ$, and $B_0 = 0.1$ T

5 CONCLUSIONS

The spin lock technique provides an effective method to generate MR images with a high tissue contrast. Magnetization transfer between protons of macromolecules and those of water molecules seems to be an important source of relaxation in the rotating frame. Slow motions of large molecules and paramagnetic substances also play an important role.

The technique may be used even at high field strengths via the utilization of the multiple slice technique or off-resonance locking pulses. The clinical potential of SL imaging is still to be evaluated. It may be assumed that it will find applications, especially in tissue characterization, abdominal imaging, and concurrent use with contrast agents and angiography.

Imaging of Wide-Band Systems by Line-Narrowing Methods

Bruno Maraviglia, Francesco De Luca,
Bruna C. De Simone, and Nicola Lugerì

Università di Roma 'La Sapienza', Rome, Italy

1 INTRODUCTION

The overwhelming majority of NMR imaging procedures and applications are based on the observation of a system of very mobile spins, whose intrinsic linewidth, $\Delta\nu$, hardly exceeds a few tens of hertz. It is well known that a number of authors have reached microscopic resolution in their images, by applying very intense gradients on small objects, owing to the 'imaging condition'¹ that relates the resolution in the image, Δr , to the gradient G and the linewidth of the system:

$$\gamma G \Delta r \geq \Delta\nu \quad (1)$$

Quite a different situation is faced when the nuclei to be imaged are constrained in a more or less rigid matrix with a correspondingly wider (of several orders of magnitude) NMR line, as is clear from equation (1): the wider the line, the greater the intensity of the gradient required for a given resolution (or, with fixed G , the poorer the resolution). In contrast, a large number of very interesting biological systems fall into this category, from rigid, crystalline solids, to polymers, ceramics, pastes, biological macromolecules, bones, and so on. Moreover, such systems show a number of very interesting phenomena related to molecular motion that can be investigated using well-known NMR relaxation parameters. Although in several systems, by means of a moderate increase in gradient intensity, one can apply standard imaging schemes, alternative approaches to equation (1) have been proposed to perform imaging also in systems whose linewidth would require exceedingly intense gradients.²

In this contribution we focus our attention on the various techniques of solid state imaging (SSI) based on the introduction of external perturbations (in excess of the 'traditional' ones, required for MRI) to the spin system, in order effectively to reduce its linewidth down to a value which makes equation (1) more easily obtainable.

2 BROADENING AND NARROWING

Why do solids give rise to NMR lines much broader than do liquids? Such a difference in behavior is due to the difference in rapidity of molecular reorientation in such systems, which allows an averaging effect on the interaction Hamiltonian to take place much more efficiently in liquids than in solids.³ It can be shown that for solid-like systems the whole

of the interaction Hamiltonian affects their NMR spectrum and, in particular, the anisotropic contribution.⁴

Line-narrowing techniques, then, tend to simulate what occurs naturally in narrow band systems: they make the spin move, following certain 'rhythms' and directions, such that the anisotropy of the Hamiltonian is drastically reduced.

Two main families can be defined among spin manipulation line-narrowing techniques, the difference relying on the space which is chosen to induce the motion of the spins. The first one, the older, is related to motion in real space, i.e. the spatial coordinates of the spins and the orientations of their vector radii (for spin-spin couplings) are made to vary in time by fast rotation of the whole solid sample around a 'magic' direction in space, for which every spin interaction tensor loses its anisotropic contribution. This technique is called magic angle spinning (MAS).

A complementary approach is followed by the second family of methods, where the motion on the system is imposed on their spin coordinates (in spin space) by means of a common precession induced by rf (pulsed or continuous; on- or off-resonance) excitation. Multipulse (MP), magic echo, and magic angle in the rotating frame (MARF) techniques are the most widely used methods in this family.

3 BASIC THEORY OF MANIPULATION IN SPIN SPACE

It is well known in quantum mechanics that whenever the Hamiltonian of a system can be decomposed into a main, time-independent part and a much weaker (interaction) contribution, the most convenient approach to the study of the system is that of the interaction representation.⁵ In NMR such an approach is, let us say, physiological, as it is translated to the geometrical view called the rotating frame (RCF). In the RCF the part of the Hamiltonian which introduces the common precession of the spins, $\mathcal{H}_0 = -\gamma B_0 \hat{I}_z$, is effectively removed (except for an eventual resonance offset ΔB_0), and the shape of the spectrum around zero frequency (or around $\gamma \Delta B_0$) is determined by the interaction Hamiltonian.

It is also well known that until the rf field $\mathbf{B}_1 = B_1 \cos \omega t \mathbf{i}_L$ is 'on', a precession at a frequency $\omega_e = \gamma B_e$ occurs around a static $\mathbf{B}_e$ field in the xz plane of the RCF, as illustrated in Figure 1 where $\mathbf{B}_e = B_1 \mathbf{i} + (\omega - \omega_0)/\gamma \cdot \mathbf{k}$. (Here $\mathbf{i}_L$ is the unit vector in the X direction of the laboratory frame (LCF); $\mathbf{i}$ and $\mathbf{k}$ are those in the x and z directions of the RCF, respectively.

Provided that the 'new' Zeeman Hamiltonian $\mathcal{H}_e = -\gamma \mathbf{B}_e \cdot \mathbf{I}$ is much stronger than the interaction ones ($\omega_e \gg 2\pi \Delta\nu$), quantization of the spin system along $\mathbf{B}_e$ can be defined. Consequently one can introduce a tilted RCF with the z' axis along $\mathbf{B}_e$ by a rotation of $\theta = \tan^{-1} (B_1/\Delta B_0)$ around y in the RCF⁶ (primed axes and unit vectors pertain to the TRCF). A further interaction representation—a double RCF—can then be introduced, in order to remove the contribution $\mathbf{B}_e = B_e \mathbf{k}'$ of the static field effectively and look at the interactions in this new frame. Of course, the interaction Hamiltonian undergoes several transformations, each one describable by a rotation. In order to see the consequences of these transformations, one has to define the rotation operators⁷ corresponding to the external perturbations leading to the DRFCF:

Figure 1 Definition of the fields and of the frames used in the text. Precession of the magnetization vector around the effective field in the RCF is also displayed

$$\begin{aligned}
 \text{LCF} &\rightarrow \text{RCF} & \hat{R}_R &= \exp(i\omega t \hat{I}_z) \\
 \text{RCF} &\rightarrow \text{TRCF} & \hat{R}_T &= \exp(i\theta \hat{I}_y) \\
 \text{TRCF} &\rightarrow \text{DRCF} & \hat{R}_D &= \exp(i\omega_e t \hat{I}_{z'})
 \end{aligned} \quad (2)$$

In terms of Euler angles, the spin dependent interaction tensor $\mathbf{A}_q$ relative to the interaction q then transforms as

$$\begin{aligned}
 A_q^{lm} &\rightarrow \hat{R}^{-1}(\omega t, \theta, \omega_e t) A_q^{lm} \hat{R}(\omega t, \theta, \omega_e t) \\
 &= \sum_{m'} D_{mm'}^l(\omega t, \theta, \omega_e t) A_q^{lm'}
 \end{aligned} \quad (3)$$

where $D_{mm'}^l$ are the elements of the l th rank Wigner rotation matrix and $\hat{R} = \hat{R}_D \hat{R}_T \hat{R}_R$. It can be shown that the transformed internal Hamiltonian in the doubly rotating frame is scaled to first order by $D_{00}^1 = \cos \theta$ or $D_{00}^2 = \frac{1}{2}(3 \cos^2 \theta - 1)$ according to the rank of the interaction, as considered in the subspace where the transformation takes place (the resonant spin subspace).

Equations (2) and (3) contain the basis for all of the known line-narrowing methods. However, they differ in the procedures followed to take advantage of these transformation properties and on the detection of the signal representative of the spin system under narrowing conditions. MP techniques introduce a cyclic succession of ‘infinitely’ short on-resonance pulses, which define a corresponding succession of differently tilted RCFs; the so-called toggling frame. In this frame, selective averaging can be obtained and observed by means of stroboscopic detection (sampling time = cycle time).

Magic echo also works on-resonance ($\theta = 90^\circ$), but with long pulses, during which the scaling of dipolar coupling by the factor $-\frac{1}{2}$ is exploited to refocus the dipolar dephasing which is usually considered irreversible.⁸

Finally, in MARF experiments one observes the evolution of the magnetization in the tilted RCF under a $\mathbf{B}_e$ which makes the magic angle with $\mathbf{B}_0$. If one considers bilinear interactions, the value is the same as in MAS experiments, $\theta_M^{(2)} = 54^\circ 44'$, while it becomes $\theta_M^{(1)} = 90^\circ$ (on-resonance field) if one wants to eliminate linear couplings. The signal can be observed only through its z' components, since it is the only axis which has no time dependence with respect to the laboratory frame. Detection can be performed directly, by means of a coil along z tuned to ω_e ,^{9,10} or by the indirect Lee–Goldburg¹¹ method.

4 IMAGING OF SOLIDS BY SPIN MANIPULATION

Each one of the above described line-narrowing techniques has been exploited, in conjunction with some spatial encoding scheme, to obtain imaging in broadband systems. The modality of introducing spatial discrimination to the system is usually very different from traditional imaging, and peculiar to the narrowing method, since the perturbing gradients should not influence the narrowing power and, more important, they have to ‘work’ in the reference frame where averaging occurs, and where the signal is detected.

4.1 MAS Imaging

The frame to be considered is the one fixed with the sample spinning at ω_R . A transverse linear field gradient, static in such a frame, can be generated by a field rotating at ω_R with respect to the LCF. Such a situation is implemented by means of two gradient coils, wound around the static surface of the rotor with their gradient directions at right angles between them and the rotation axis. Once fed by quadrature currents oscillating at the same rotor angular frequency, the composition of the resulting oscillating fields gives the desired linear rotating gradient. Since the geometry of the coils is dictated by that of the rotor, the gradient coils give rise to a field gradient tensor, the effect of which is a distortion of the projections, unless attention is paid, to both the geometrical arrangement of the coil axes and the intensity and phase of the current flowing in them.¹²

Projection reconstruction (PR) and two-dimensional Fourier transform (2D FT) imaging procedures may be used with this method. In each case there is a need for an accurate control of the phase φ and $\varphi + 90^\circ$ between each component of the gradient and the reference frequency extracted from the rotor spinning velocity by an optical detector.

If φ is incremented in small steps, PR can be straightforwardly implemented; 2D FT requires a phase change ($\Delta\varphi = 90^\circ$) in each component of the current in order to switch the gradient direction from encoding to read-out, following the incremented time imaging scheme of Figure 2.¹³ Since MAS narrowing power is limited by the spinning frequency (up to about 10 kHz), which has to be greater than the bandwidth of the sample, this method can be usefully applied to solid systems with small or intermediate bandwidths, although several interesting developments toward a larger variety of samples have recently been proposed, including combination with MP techniques and spectroscopic investigations on ^{13}C with sideband suppression.¹⁴ Interesting methods of contrast and resolution enhancement have also been proposed.¹⁵

4.2 Imaging by Multipulse Narrowing

In MP techniques one has to follow (and detect) the evolution of the spin system in the toggling frame, as defined by the sequence chosen. Several techniques have been proposed; in general, every MP sequence can be combined with gradient schemes to obtain SSI, mainly differing in how and when the gradients are applied within the whole imaging scheme, in order to match as well as possible the requirements of narrow-

applied in the windows indicated in Figure 4, either in the free evolution period (static gradient, G_0) or during the rf excitation (rf gradient, G_1). The method can also be made sensitive to several contrast parameters, leading in some cases to images of the NMR parameter distribution in the samples.^{2,23}

4.4 MARF Imaging

The last technique which is going to be described is the one we have been developing since its presentation in 1986 as a means of obtaining spin mapping of narrowed band solids.²⁴ The line-narrowing MARF technique has been known since 1963, when Lee and Goldburg¹¹ proposed a method to reconstruct, starting from ordinary FIDs of solids, the evolution of a system in the TRCF under magic angle conditions. There are a large number of experiments where the evolution of the spins in the rotating frame is studied, especially involving relaxation in solids, and each one can be considered as a ‘consequence’ of the historical work of Redfield on the saturation in solids.⁵ The approach to imaging by the MARF method, like the preceding ones, relies on the combination of the narrowing sequence with well defined field gradients.

Here one has to observe what happens in the doubly rotating frame, as defined by equation (2), since in that frame the interaction Hamiltonians are scaled by $D_{00}^2(\theta)$ or $D_{00}^1(\theta)$. Spatial encoding must then be introduced in the signal coming out from this frame, i.e. B_e should become space dependent. Concerning ourselves with bilinear interactions only, it is then clear that a static linear field gradient would not be sufficient because it would degrade the narrowing efficiency, as a consequence of the spread in tilt angles over the sample. B_e intensity variation and a tilt angle uniformity is instead obtained by an effective field gradient $G_e = G_1 + G_0$, given by the composition of an rf ($G_1 = \partial B_1/\partial r$) and a static gradient ($G_0 = \partial B_0/\partial r$), whose intensities match a further ‘magic’ condition ($G_1/G_0 = \tan \theta_M = \sqrt{2}$).

Two detection methods have been mentioned. In the direct one, a very sensitive coil with its magnetic axis along z is tuned to ω_e and used both to induce transitions between the RCF Zeeman levels and to detect the precession of the perturbed system around B_e in the return to equilibrium. Excitation is performed by the so called ‘audio pulses’ $B_2(t) = 2B_2(t) \cos \omega_e t \mathbf{k}$, which provide the transverse component in the TRCF $B_{2\perp}(t) = B_2 \sin \theta_M \cos(\omega_e t + \gamma) \mathbf{i}'$ necessary to generate the observable M_{xy} . Every NMR pulse sequence among the ‘traditional’ ones can, in principle, be reproduced in the TRCF. The MARF spin echo sequence which we implemented to perform imaging on crystalline adamantane is sketched in Figure 5(a).²⁵ The first ‘spin lock’ pulse is used to tilt M_0 with z to z' (a θ_M pulse about 63° out of phase from the long B_e pulse) so that the initial conditions for TRCF experiments are the same as in traditional NMR ($M_z = M_0$, $M_x = M_y = 0$). The collected signal can also be demodulated by means of the audio-frequency (af) reference ω_e in order to visualize the behavior of the system in the DRCF. In Figure 5(b) the results of a PR procedure performed on two adamantane phantoms by the MARF echo direct detection method are shown. Due to the possibility of the sample having to withstand long measurement times, and in order to avoid excessive probe complexity, PR by sample rotation along a direction perpendicular to the single

Figure 5 (a) Sequence for MARF spin echo imaging. Direct detection in the RCF provides the echo signal of the ‘narrowed’ solid. Its FT gives the projection along G_e . (b) Proton images of two adamantane samples ($\Delta\nu \approx 18$ kHz) obtained by reconstruction of 16 projections. The effective field intensity was approximately 17 mT m^{-1} , for a resolution of about 1 mm. (Reproduced by permission of Academic Press from De Luca et al.²⁵)

gradient direction has been chosen, although 2D FT schemes are under test.

The second method is potentially very promising among the various SSI techniques. It differs from the previous one only in the way of looking at the spin system in the TRCF. As Lee and Goldburg proposed, the TRCF FID can be reconstructed by means of several experiments where the spins are made to precess around B_e for incremented time intervals $n \Delta t$ ($n = 0, \dots, N$). $M_z(n \Delta t)$ can be read indirectly by a 90° pulse applied far enough from $n \Delta t$ to let any residual transverse magnetization be destroyed. The $(N + 1) M_z$ values so obtained represent the TRCF FID sampled with frequency $1/\Delta t$, and the spectrum is obtained by direct FT. If the evolution in the TRCF occurs under the presence of the above described G_e ,

Figure 6 (a) Timing diagram of Lee-Goldburg MARF imaging. Each projection is obtained by N shots with a regularly increasing rf excitation in the magic angle condition. (Reproduced by permission of Società Italiana di Fisica from Luger et al., *Proc. Int. Summer School "E. Fermi", Course CXXIII, Varenna, 1993*). (b) PR proton image of a composite sample of polyethylene (P, length = 35 mm), adamantane (A, length = 25 mm), and Vulkollan (V, length = 15 mm) layers separated by Teflon spacers (T). Polyethylene is a rigid polymer ($\Delta\nu \approx 40$ kHz); while Vulkollan is a relatively narrow-band elastomer ($\Delta\nu \approx 1.5$ kHz). Eighteen projections were taken under a G_e of about 25 mT m^{-1} . The corresponding resolution was estimated to be about $200 \mu\text{m}$

one can obtain spatial discrimination of the spectrum. The Lee-Goldburg imaging sequence is illustrated in Figure 6(a). Again PR is the easiest imaging method to use in such conditions, and by this procedure we obtained the well resolved image ($\Delta r \approx 200 \mu\text{m}$) of Figure 6(b).

It should be noted that, apart from a slight complexity in the probe arrangement, the technique is very easy to implement, since it is based on repeated LCF experiments, with a consequent relatively high signal-to-noise ratio. A home-made computer-assisted apparatus ensures stability, reliability and rapidity of the whole sequence;²⁷ it also allows a wide variety of preparation and reading pulse sequences to be built instead of the basic method of Figure 6(a). These sequences are used to introduce sensitivity to different relaxation parameters. In particular, T_1 -, T_2 - and $T_{1\rho}$ -weighted images of rigid polymers and crystalline solids have been obtained, leading to interesting data on the slowest molecular motions in such systems.^{28,29}

Imaging Techniques for Solids and Quasi-Solids

John H. Strange and Morley R. Halse

University of Kent, Canterbury, Kent, UK

1 INTRODUCTION

Liquids, and materials of biological interest such as water and fat, typically have T_2 values in the region of 100 ms or longer and the success of medical MRI has amply demonstrated our ability to image such materials. As the target material becomes more solid-like, however, the problems of imaging become more severe. As well as an immediate problem of lower resolution, there is also a general deterioration in signal-to-noise ratio. It is an unfortunate fact that short T_2 materials do not have a correspondingly short T_1 . Since the signal-to-noise ratio in the final image depends critically on the fraction of time that signal is available, it is actually the generally unfavorable ratio of $T_2:T_1$ in solids as much as the inherently short T_2 itself that is the root cause of the problem of broadline imaging.

The standard technique of reducing the T_1 of pure water by doping with paramagnetic relaxation centers is a common example in which the T_1 of the material can be artificially reduced, but such treatment is not generally available for most applications. All attempts so far have therefore been directed at increasing T_2 by adapting the standard line-narrowing techniques of solid state NMR (e.g. MREV, WAHUHA and their many variants, as well as magic angle spinning) to imaging.

These techniques are technically very demanding. A second 'direct' approach has been simply to accept the broadline and adjust the imaging parameters such as echo time, and in particular, gradient strength, so as to generate an image within a timescale of the order of T_2 . This 'direct' approach has proved itself particularly suited to the more nonmedical materials science applications where short imaging times are not a restriction. One sophisticated variation uses the large enhancement in effective field gradients that result in multiple quantum NMR.

As well as the brief descriptions offered in this short article, the reader is referred to the various reviews on the subject by Blümmler and Blümich,¹ Miller et al.,² and Strange,³ the articles on solid state imaging by Veeman et al. in the book 'Magnetic Resonance Microscopy' by Blümich and Kuhn,⁴ and to Callaghan's book.⁵

At present, no one method has emerged with a clear advantage and the story of solids imaging is one of parallel progress being made steadily on a number of fronts. In practice, the choice of technique is likely to be determined by consideration of the severity of the broadline problem, the necessity to preserve spectral information such as chemical shift, the physical nature of the specimen, or the need to apply slice selection.

2 MRI IN SOLIDS: THE PROBLEM STATED

We first give a basic analysis of the imaging resolution expected in MRI. Consider two groups of protons separated by a distance dz in a gradient $G_z = dB_z/dz$ applied in the z direction as shown in Figure 1(a). The difference between the Larmor frequencies of the two groups of protons will be $\gamma dz G_z$. After a 90° pulse, we therefore have the situation shown in Figure 1(b) in which the received signal will be a beat pattern within a decaying envelope of time constant T_2 . The FT of this FID will give two peaks as shown in Figure 1(c). The decay of the envelope will broaden each line by an amount $1/\pi T_2$ Hz. The shorter T_2 is, the greater is the broadening. The limit of resolution will occur roughly when the width of each line is comparable to or greater than their frequency separation, i.e.

$$1/\pi T_2 \sim \gamma dz G_z \quad (1)$$

For a typical medical MRI scanner, the image echo time TE is designed to fall well within T_2 so that signal is not lost. Under these circumstances, the broadening of the line due to each group of protons in Figure 1(a) is due to the finite data capture window ($\sim TE$) rather than the T_2 decay itself. Thus

Figure 1 Illustration of linewidth limited resolution in NMR imaging (see text)

$$dz \sim 1/\gamma G_z \pi TE \quad (2)$$

With $TE = 20$ ms and $G_z = 10$ mT m⁻¹ we find that $dz \sim 60$ μ m.

Now consider the situation in a solid where T_2 may be 100 μ s or less. Even if we relax the signal-to-noise consideration and take $TE = T_2$, equation (2) predicts a resolution (with $G_z = 10$ mT m⁻¹) of little better than 10 μ m.

The resolution can obviously be improved by increasing the gradient. But increasing G_z will increase the spread of Larmor frequencies generated by the extremities of the sample. If the field-of-view is to be maintained, the receiver bandwidth will have to be increased and the receiver signal-to-noise ratio will suffer. The inevitable conclusion is that the direct approach leads to a reduced signal-to-noise. Longer imaging times are therefore required if signal-to-noise ratios are to be restored by signal averaging.

The various schemes put forward to circumvent this basic truth are now discussed.

3 IMAGING METHODS

3.1 Multipulse Line Narrowing

The earliest multipulse sequences designed to average out the dipole-dipole interaction and preserve chemical spectroscopic information in solids were those of Waugh and Mansfield and their collaborators.⁶ These sequences artificially provide the essential time dependence required to average out the magnetic interaction between neighboring dipoles. Many variants have been designed which not only cancel the dipole-dipole interaction, but also successfully cancel other broadening interactions such as anisotropic chemical shift. Sequences are usually designed to suppress the effects of magnetic field inhomogeneity broadening as well.

But therein lies the crux of the problem with the 'standard' line-narrowing approach. Sequences which cancel the effects of field inhomogeneity are clearly of no use in imaging unless they can allow a separation of magnetic inhomogeneity and applied field gradient effects. What is required is a pulse sequence that is tolerant to field offset: i.e. one which produces line narrowing in the presence of a field gradient, yet essentially preserves the gradient interaction. The solutions which have been proposed require an advanced understanding of quantum mechanics and are tricky to implement in practice. However, one of the underlying principles of all of these methods is simply stated: make sure that the imaging gradient is zero during the rf pulses. Two approaches have been suggested.

The first is due to McDonald and Tokarczuk who proposed a 6-pulse (ZIG-ZAG) sequence⁷ in which the pulses are timed to coincide with the zero crossing of an oscillatory imaging field gradient. Remembering that multipulse sequences attain their full efficiency only when the pulse separation is much less than T_2 , typical interpulse times are of order 20 μ s. Thus a high frequency oscillatory imaging gradient (~ 25 kHz) is required. Several imaging schemes have been demonstrated and an example of an image of two 5 mm cubes of the organic crystal adamantane⁸ is shown in Figure 2. The image was formed from a two-dimensional FT using a modulated gradient

Figure 2 Two-dimensional FT image of two 5 mm cubes of adamantane obtained using the ZIG-ZAG multipulse line-narrowing technique. (Reproduced by permission of Elsevier Science B.V. from P. J. McDonald and A. R. Loneragan⁸)

technique. Adamantane has a linewidth of 20 kHz at room temperature. The normal T_2 has been extended to several milliseconds by the ZIG-ZAG sequence.

The second approach, and currently regarded as the most successful of all the solids imaging schemes proposed to date, has been that of Cory et al.⁹ They circumvent the problem of the simultaneous application of rf and imaging gradients by applying the gradients only in very short bursts between the rf pulses. Their second-averaging method can produce astonishing results, as the high-resolution multipulse images of sections through a polyacetal (Delrin) phantom¹ shown in Figure 3 testify. Although this method shows that, in principle, the problem of solids imaging has been solved, very powerful rf and gradient amplifiers are required together with very low inductance imaging gradient coils. The equipment is expensive and well beyond the resources of most laboratories. One would therefore have to say of these line-narrowing techniques, that while their efficiency is impressive, they are difficult to set up and their use is not yet routine.

3.2 Magic Angle Spinning (MAS) Imaging

Magic angle spinning is a mechanical line-narrowing technique first proposed by Andrew and Eades¹⁰ in which the sample is rotated at high speed at an angle of 54.7° to the B_0 field. At this angle, the dipole-dipole interaction can be reduced and eventually averaged to zero provided the speed of rotation is comparable to or larger than the NMR linewidth. Although MAS spinners are now a standard facility on most spectrometers, the proposal that MAS might be modified to allow simultaneous imaging has only recently been explored because of the technical demands. The aim is to generate a rotating imaging gradient field matched in frequency and phase

Figure 3 Multipulse image using second-averaging of a Delrin (polyacetal) phantom formed from $64 \times 64 \times 16$ voxels obtained at 400 MHz. Voxel size is $92 \mu\text{m} \times 92 \mu\text{m} \times 625 \mu\text{m}$. Four sections through the sample (given schematically above) are shown. (Reproduced by permission of D. G. Cory)

to that of the MAS rotor. Under such circumstances, the gradient field will appear stationary with respect to the sample and imaging becomes relatively simple. Clearly such a scheme imposes severe restrictions on sample size and strength and its use is therefore always likely to be limited. An example of two such MAS images taken from the work of Cory et al.¹¹ is shown in Figures 4(a) and (b). The experiment is tolerant of small errors in setting up and effects due to spinning sidebands can be eliminated. Available rotation rates will not, however, narrow the broadest lines. To overcome this problem, it has been necessary to combine MAS with multipulse line-narrow-

Figure 4 Ring of polybutadiene imaged by MAS showing (a) distortion due to chemical shift, (b) improvement by deconvolution. (Reproduced by permission of Academic Press from D. G. Cory et al.¹¹)

ing sequences such as MREV-8. This has been successfully demonstrated for polyethylene particles of about 2 mm in size by Conradi et al.¹² The application of this technique to plastically deformable solids is clearly a problem as a spinning rate of 5 kHz can produce centrifugal acceleration of $10^5 g$!

Synchronous rotation of sample and gradient allows either radial scanning of k -space to produce an image by filtered back projection reconstruction or two-dimensional Fourier transform imaging. It is also possible to scan k -space by rotating the gradient at a different frequency to that of the sample rotation. For more detail and variations of the MAS method, readers can consult the reviews by Blümli and Blümli¹ and by Veeman et al. in Blümli and Kuhn.⁴

Although MAS methods are less successful in line narrowing, an attraction of this method for broadband MRI is that spectroscopic information such as the chemical shift is preserved and ^{13}C spectroscopic imaging is attractive.

3.3 Rotating Frame Imaging

This technique is another example of the extension of a solid state line-narrowing method to imaging. The idea is to take the main B_0 field off-resonance and apply rf of suitable amplitude so as to generate an effective field B_{eff} at the magic angle in the rotating frame (MARF). The net result is that the magnetization is spin locked about the effective field at the magic angle and line narrowing is achieved.¹³ For imaging, a gradient in the resonance offset is established across the sample while at the same time ensuring that the effective field remains everywhere at the magic angle. This is done by suitable modulation of both the B_0 and B_1 fields. Compared with the MAS method, corresponding rotation rates are higher and therefore line narrowing is more efficient. Another advantage over MAS is of course that the sample itself remains static. Sensitivity is however low, corresponding to the low (audio) frequency of resonance in the effective field, and is directly related to B_1 .

A variation of this experiment, whereby signal is only observed after the pulsed rf and gradient encoding and is acquired slowly point-by-point, requires varying the length of the spin lock and gradient pulses. The signal is observed at radiofrequencies with the corresponding advantages of high signal-to-noise. Technically, the equipment is demanding, as specially matched gradient coils are required. An example of a rotating frame image of compressed adamantane taken from de Luca et al.¹⁴ is shown in Figure 5.

Note finally that if θ denotes the angle between B_{eff} and the main B_0 field, the isotropic chemical shift and gradient interactions scale as $\cos \theta$, whereas the anisotropic interactions scale as $(3 \cos^2 \theta - 1)$. Thus MARF can retain some aspects of the isotropic chemical shift, while averaging the anisotropic parts to zero.

Another example of rotating frame imaging is that proposed by Barrall et al.¹⁵ and by Woelk et al.¹⁶ and is a beautiful example of lateral thinking. The method exploits the $1/r$ dependence of the magnetic field surrounding a straight wire carrying a current to provide a gradient of the rf field. The wire forms part of a resonant rf cavity, and the sample to be imaged is placed near to the wire or may be deposited or painted onto the wire. When an rf pulse is applied to the wire, the resulting magnetization rotation angle in the sample will be inversely proportional to radial distance. By applying an rf

Figure 5 Phantom of organic crystalline material formed from compressed adamantane imaged using MARF. (Reproduced by permission of Academic Press from F. de Luca et al.¹⁴)

nutration sequence consisting of rf pulses interleaved with data acquisition points, the total signal $S(t)$ will be given by¹⁵

$$S(t) = \int \omega(r) \rho(r) \sin[\omega(r)t] dr \quad (3)$$

The radial spin density distribution $\rho(r)$ can be readily calculated from $S(t)$. The method is essentially the same as MARF, except that the nutation is about y' in the rotating frame rather than the magic angle and so there is no consequent benefit from line narrowing. However the rf gradients can be made very large near the wire and the quoted resolution is of the order of $20 \mu\text{m}$ for a Teflon sample.

3.4 Magic Sandwich Echo Imaging

This technique has been discussed by Matsui et al.¹⁷ and by Demco et al.¹⁸ The basic sequence $90_x - \tau - 90_y - 2\tau - 90_x - 2\tau - 90_x - \tau - 90_y - \tau - \text{echo}$, first described by Rhim et al.,¹⁹ produces a 'magic echo' after a time 6τ . By repeating the sequence, a train of magic echoes can be generated decaying with a much extended FID. The application of imaging gradients and data acquisition are undertaken in the appropriate windows of a 24τ sequence. The scheme appears to be much more robust to experimental imperfections in timing and phase errors than the other multipulse sequences and is considered to be one of the most promising broadband imaging schemes suggested to date. An example of a three-dimensional magic

Figure 6 A three-dimensional magic echo phase-encoded image of a hexamethylbenzene (HMB) phantom. Voxel resolution is $300 \mu\text{m}$. A drawing of the sample is shown at the top. (Reproduced by permission of Academic Press from S. Hafner et al.²⁰)

echo phase-encoded image of a hexamethylbenzene phantom taken by Hafner et al.²⁰ is shown in Figures 6(a) and (b).

3.5 Stray Field Imaging (STRAFI)

This technique, pioneered by Samoilenko et al.,²¹ is a successful example of the 'direct' approach and bears some similarity to the sensitive plane method developed many years ago by Hinshaw. It exploits the fact that a very large field gradient is naturally available in the fringing field of a superconducting magnet. In a region displaced well away from the magnet center and in some cases physically outside the magnet altogether the gradient can approach 40 T m^{-1} for a 4.7 T magnet. The gradient is of course static, so the sample has to be moved through the gradient by means of stepper motors and the image reconstructed by back projection. The width of the sensitive plane dz is given by

$$\gamma G_z dz = 1/T_{90} \quad (4)$$

i.e.

$$dz = 1/\gamma G_z T_{90} \quad (5)$$

Thus dz is simply the spectral width of the rf pulse in Hz divided by the gradient in Hz m^{-1} . With a 90° pulse of $20 \mu\text{s}$ and a gradient of 25 T m^{-1} , equation (5) predicts a resolution of $50 \mu\text{m}$. With such a huge gradient, the FID is extremely short, so 90_y pulses are used to hold up the magnetization by generating a train of solid echoes.²² The signal from the slice is simply proportional to the integrated sum from all of the echoes.

The method has two interesting additional features. The first is that because the sample is moved through the sensitive slice during imaging, T_1 saturation effects can be avoided and the pulse sequence repetition rate can be much faster than dictated by the normal $5T_1$ rule. Signal averaging can be carried out by ramping the sample through the sensitive slice many times.

The second advantage is that STRAFI suppresses susceptibility artifacts. These occur in any sample at the boundaries between regions of differing magnetic susceptibilities. At such boundaries, small changes in the internal B field are generated proportional to $B_0(\chi_1 - \chi_2)$. Since the distance over which this change in internal field is generated can be measured in μm , even if the differences between the susceptibilities is only 10^{-5} , the internal gradients generated can be enough to distort the image. With STRAFI, however, the very large imaging gradient ensures that these internal gradients are rendered negligible. It is therefore capable of imaging materials containing paramagnetic impurities such as soil or rock (see, for example, Kinches et al.²³).

The method has progressed from early one-dimensional profiles across a group of human hairs showing the μm resolution capability of the method, to full high resolution three-dimensional images of small, solid, manufactured components.

Clearly STRAFI has a promising future as a materials science tool but because of the time penalty, it is most likely, in our opinion, to find its greatest use in the generation of one-dimensional profiles. An example from Perry et al.²⁴ showing the ingress of acetone vapour into poly(vinyl chloride) (PVC) is shown in Figure 7. The profile is due to a combination of mobile, absorbed acetone ($T_2 \sim 25 \text{ ms}$), swollen PVC ($T_2 \sim 2 \text{ ms}$), and rigid PVC ($T_2 \sim 90 \mu\text{s}$)

3.6 Oscillating Field Gradients

This method is the second example of the direct approach and has been developed over the years by the authors and others since an early paper by Cottrell et al.²⁵ The method has found most application in the semi-solid regime covering T_2 values in the millisecond region. A large oscillating gradient with a period T , whose magnitude defines the attainable image resolution, is established in a gradient coil. After any initial transients have decayed, a 90° rf pulse is applied at the moment of zero crossing of the gradient field. Provided the rf pulse is very short, the gradient will be sensibly zero throughout the pulse and all spins in the sample will receive a 90° rotation. After one cycle of the gradient field, a gradient echo forms. Due to the restriction of the T_2 decay, the period T of the gradient field must be of the order of T_2 . As a consequence of the varying gradient, sampling of the echo in the data capture window from $T/2$ to $3T/2$ at a uniform rate results in a nonlinear coverage of k -space. Fortunately compensation for this effect can be achieved in software, and a one-dimensional

Figure 7 Acetone vapor diffusing into PVC. The image, obtained by STRAFI, shows the acetone concentration variation from 0 to 3 mm penetration superimposed on the rigid PVC signal from 0 to 11 mm. (Reproduced by permission of Butterworth Heinemann Ltd © 1994 from K. L. Perry et al.²⁴)

profile can then be obtained from an FT in the usual way. Two-dimensional images can be obtained by back projection.

The method has the merit of great simplicity, but it also has its disadvantages and its traps for the unwary. The main disadvantage is that the large gradients necessitate the use of a large receiver bandwidth. As outlined in Section 2, this inevitably leads to a degradation in signal-to-noise ratio. An example of a back projection image taken of a rubber sample with a T_2 of approximately $700 \mu\text{s}$ is shown in Figure 8.

The method can also suffer from the presence of a very small dc bias in the gradient current which can severely attenuate the amplitude of the echo if the k -space trajectory fails to return to the origin. All dc coupled amplifiers suffer to a greater or lesser extent from varying dc offsets and these offsets can have disastrous effects on the image. To prevent this happening, and at the same time to eliminate many of the

effects due to the inductance of the gradient coils, a capacitor is used to series resonate the gradient current.

One further disadvantage of the method is that since it uses a *gradient* echo, the images can be degraded by an intensity modulation effect due to phase shifts caused by inhomogeneities in the main B_0 field. Unlike a spin echo, there is no automatic compensation for B_0 inhomogeneity. A further consequence is that in its simplest form, the method is limited to the study of materials with a T_2 of less than the T_2^* of the magnet.

Despite these disadvantages, oscillating gradient imaging has proved to be of considerable practical utility. Several variants of the basic method have been proposed. In one scheme by Mat Daud and Halse,²⁶ imaging is carried out with two oscillating gradients, one having twice the period of the other. The second gradient is used for phase encoding. Working out the two-dimensional (2D) k -space trajectories for this data set is even more complicated, but the final step involves a 2D FT and leads directly to an image in the normal way. An example of a ^{19}F image of a 'C' shaped piece of Teflon is shown in Figure 9. The T_2 here is approximately $60 \mu\text{s}$. The peak gradient was 1 T m^{-1} and the imaging time was 20 min.

The solid echo ($90_x - \tau - 90_y$) arising from a refocusing of the dipole-dipole interaction can of course be used to extend the signal in oscillating gradient imaging as well as in STRAFI. An example of an extended train of echoes from rubber³ for which $T_2 \sim 500 \mu\text{s}$ is shown in Figure 10. The 90_y pulses are applied at the zero crossing of every odd gradient cycle (thus unfortunately destroying the odd-numbered gradient echoes) but leaving the even-numbered echoes unaffected.

Note that in Figure 10, although the train of solid echoes extends to $\sim 10T_2$, in this example, the decay was in fact limited by the inhomogeneity of the magnet. In practice, therefore, for semi-solids such as rubber, it is found that a series of 180_y pulses is more beneficial for extending the decay envelope. Compensating for the inhomogeneity of the B_0 field in this way does not extend T_2 . However, when the 180_y pulses are closely spaced, they can be regarded as generating a form of average spin locking field in the y' direction in the rotating frame. The decay of the magnetization therefore tends to $T_{1\rho}$.

Unfortunately, extending the decay by generating multiple echoes in this way cannot be exploited to increase the image

Figure 8 Image of 11 pieces of 1 mm diameter rubber in a Teflon holder obtained from echoes formed by the direct application of large oscillating field gradients. (Reproduced by permission of The Royal Society, London from J. H. Strange³)

3.8 Deconvolution

An image of any object is of course simply that of the original object convolved with an imaging point spread function. If the image could be correspondingly deconvolved, the original image can be recovered. One of the earliest attempts at this approach was that of Suits and White³¹ who ingeniously incorporated the deconvolution procedure into the back projection algorithm itself. Their measurements demonstrated the feasibility of solid state diffusion studies. Deconvolution can also be used to unscramble the effects of chemical shift. Butadiene, for example, contains two chemically distinct protons. Figure 4(a) shows a MAS image of a sample of butadiene in which the two resulting images are misplaced. In Figure 4(b) the image has been deconvolved.¹¹ Another approach, closely allied to deconvolution, is maximum entropy (ME). Here, the fitting is done by the forward convolution of an arbitrary starting function (e.g. a completely uniform gray image) followed by comparison with the observed blurred data. Iteration takes place until a satisfactory fit is obtained consistent with the signal-to-noise, but no better. Of all such possible fits, the ME method chooses the image with the least detail. The technique is now well established as a useful tool for the deconvolution of high-resolution spectra. The problem with solids imaging however is that not only is the point spread function proportional to $1/T_2$ and therefore very large, but, more importantly, solids imaging inevitably gives a poor signal-to-noise ratio. Under these circumstances, deconvolution methods can be unstable and prone to failure. It nevertheless remains a technique that can be applied to sharpen up any image and may yet have a future place in solids imaging.

4 OTHER CONSIDERATIONS

4.1 Slice Selection

In Section 3, brief references have been made to the feasibility or otherwise of incorporating slice selection into the various imaging schemes. In this short section, we briefly review the general principles behind broadband slice selection.

The standard methods of slice selection in MRI require the application of a sinc-shaped rf pulse in the presence of a magnetic field gradient to excite nuclei within the slice. The gradient is then removed and orthogonal gradients applied for spatial encoding. Since this process must occur on a timescale of much less than T_2 , it creates very serious problems for short T_2 materials. Several approaches have been developed to overcome the problem and some are considered by Cottrell et al.³² and also by Rommel et al.³⁰ The basic idea is to spin lock the magnetization in the presence of a slice selection gradient. A comprehensive discussion of slice selection in solids can be found in the reviews by Blümich and Blümich¹ and by Kimmich et al. in Blümich and Kuhn.⁴

An alternative solution is to vary the encoding gradient over all directions in 3D space and use back projection or Fourier reconstruction to obtain a 3D image from which any slice, or indeed any voxel, can be computed. The method is very time consuming, but for inanimate matter the advantage of simplicity may be paramount.

Another relatively simple approach is to saturate all but the selected slice using shaped rf pulses with appropriate gradients. The unperturbed slice is then subjected to a 'solids' imaging sequence. Widelane samples require wideband irradiation and high power rf pulses are essential. The long T_1 values that are often associated with such samples are an advantage here as there is then time to change the large field gradients from slice select to encode mode.

Another approach, similar in effect to selective saturation, is 'spin lock-induced slice selection' (SLISE) which employs a hard 90° pulse followed by a spin lock pulse in the presence of a gradient. A selected slice only is spin locked and this decays with a time constant $T_{1\rho}$ which is typically much longer than the non spin-locked magnetization decay time ($\sim T_2$). SLISE is valuable for localized spectroscopy.

Finally, it should be noted that broadband imaging by MAS has yet to employ satisfactory slice selection, whereas, by its very nature, STRAFI incorporates slice selection automatically.

4.2 Contrast and Relaxation Filters

For solids and liquids alike, the basic imaging method portrays a map of nuclear spin density. Relaxation time mapping, i.e. the visualization of the spatial variation in a particular relaxation time, can be very valuable in distinguishing the differing character of parts of a sample. Relaxation times, particularly T_2 and $T_{1\rho}$, often have a much wider variation in solid-like samples than in mobile liquids. Their temperature and pressure dependence is also visually much greater. Relaxation time mapping, and the use of these parameters as filters,³³ has been clearly demonstrated for broadband materials, particularly polymeric materials, and exploitation of such techniques is to be expected in the future. When used to characterize materials, contrast ratios are often more important than signal-to-noise ratios. An example of a $T_{1\rho}$ -weighted image of oxidatively aged rubber can be found in the article by Kuhn in Blümich and Kuhn.⁴

The multiple echo method version of large oscillating gradient imaging can also be put to good use in ' T_2 mapping'. Referring to Figure 10, one can see that at least seven echoes are available from which seven images can be obtained with imaging times ranging from 0.4 to 3 ms. By comparing the decay in signal intensity from the same pixel in each of the seven images, a true T_2 map can be produced. This technique has been used by Halse et al.³⁴ in a study of the ingress of decane into rubber. T_2 maps were generated showing the increase in T_2 of the rubber as it softened.

5 CONCLUSION

At this time it appears that a specialized multipulse sequence will produce the sharpest image in a small, solid object. The much simpler magic echo appears more robust, but carries a time penalty as the effective T_2 is not so efficiently increased. Of the 'direct' methods, STRAFI is capable of excellent results in small, static, easily manipulated objects. Although there is a time penalty involved in being restricted to the use of only one fixed gradient, the selective nature of the rf excitation means that the usual ' $5T_1$ ' rule can be circumvented. For moderately broad lines, the 'direct' methods employing

oscillating gradients combined with a sustaining pulse sequence are very promising and can be adapted for larger samples and in vivo measurements. Applications of broadband sample imaging have been directed at polymeric materials in which cross-link density, fluid ingress and chemical reaction effects have been studied. Other examples include the study of diffusion in the solid state and defect density in crystalline solids.

1 INTRODUCTION

NMR microscopy is one of the newly emerging tools for the high-resolution three-dimensional imaging of live animals and plants for biological as well as medical research. More recent developments include application of the technique to such things as porous materials and microflow, the study of which is essential for oil research. One of the main attractions of NMR microscopy is that it is a truly noninvasive three-dimensional high-resolution imaging tool with which micrometer resolution can be achieved. However, NMR imaging, especially NMR microscopy, has a number of formidable drawbacks, namely: a small signal-to-noise ratio due to the inherently small object size; diffusion and bandwidth limitations; and other inhomogeneity effects such as chemical shifts and susceptibility effects.^{1–10} Some potentially feasible solutions to the above problems have been addressed by a number of researchers.^{1,9,11}

Among other problems, that of diffusion due to the random Brownian motion of (water) molecules appears to be one of the fundamental physical limitations to NMR imaging, especially in high-resolution microscopy where these molecular diffusion distances are close to the resolution limits.^{1,7} Although the diffusion effect in NMR has been studied extensively,^{12–17} the effect on NMR microscopy has not yet been observed experimentally due to the current limitations of NMR microscopes. Theory, however, suggests substantial resolution broadening in NMR microscopy if molecular self-diffusion prevails, especially when dealing with molecules that have large diffusion coefficients.^{1,7,11} This article describes the details of the resolution limits, especially those due to diffusion effects, in NMR microscopy. The discussion given covers: (1) the effects of phase variation due to molecular self-diffusion during data acquisition; (2) the effects of signal attenuation and related line broadening; and (3) some diffusion effects of molecules which, when confined within boundaries or walls, exhibit anomalies in resolution in NMR microscopy. The first two effects are based on free water molecules while the third is based on the model of water molecules confined by boundaries, which have significant physical consequences. Before discussing the effects of diffusion on the resolution of microscopic imaging, the other resolution limits are discussed briefly, namely the resolution limit due to the phase factor, which is related to the finite bandwidth of the imaging instrumentation; that is, the available gradient strength and acquisition time, both of which are intimately related to the diffusion effect.

2 RESOLUTION LIMITS DUE TO FINITE SYSTEM BANDWIDTH

Let us first assume that the signal-to-noise ratio is sufficiently high and the detection system is ideal, i.e. there is no uncertainty in the measurement. Since NMR imaging is a phase-encoding technique, it is natural to consider the minimum detectable phase difference to be a function of the signal separation between two points (resolution), the gradient strength G , and the data acquisition time T_{acq} . The two encoded phases during the acquisition time, or period (T_{acq}), for a pair of objects located at positions r_1 and r_2 are given by

$$\phi(r_1) = \gamma r_1 \int_0^{T_{\text{acq}}} G(t') dt' \quad (1)$$

and

$$\phi(r_2) = \gamma r_2 \int_0^{T_{\text{acq}}} G(t') dt' \quad (2)$$

respectively, where γ is the gyromagnetic ratio. From these two equations, the well-known bandwidth limited resolution can be defined using the phase difference between two points:

$$\Delta\phi_r = \phi(r_1) - \phi(r_2) = \gamma(r_1 - r_2) \int_0^{T_{\text{acq}}} G(t') dt' = \gamma \Delta r G T_{\text{acq}} \quad (3)$$

where γ is the gyromagnetic ratio, and Δr is the spatial difference between two points r_1 and r_2 . In equation (3), a constant amplitude gradient G is assumed. From equation (3) the bandwidth limited resolution can now be defined as

$$(\Delta r)_B = \Delta\phi_r^{\text{min}} / (\gamma G T_{\text{acq}}) \quad (4)$$

where $\Delta\phi_r^{\text{min}}$ is the minimum detectable phase.

Equation (4) is a fundamental relationship representing the intrinsic resolution as a function of the minimum detectable phase and the gradient-time product. The minimum detectable phase $\Delta\phi_r^{\text{min}}$ is dependent on the reconstruction algorithm. For example, $\Delta\phi_r^{\text{min}} = \pi$ if Fourier imaging is used with a half-echo data set. For a given minimum detectable phase, the resolution can be improved by increasing the gradient-time product. As implied in equation (4), relatively large gradients (0.1–1 mT m⁻¹) will be needed for microscopic resolution imaging. Since $(\Delta r)_B \gamma G$ corresponds to the bandwidth of the microscopic imaging system, resolution related to this limitation is often called ‘bandwidth limited resolution’, and we will use this term henceforth. Examples of the bandwidth limited resolution discussed above [e.g. equation (4)] are given in Figure 1, where the relationship between the gradient strength G and data acquisition time T_{acq} are given for 1 μm and 10 μm resolution.

3 RESOLUTION LIMITS DUE TO DIFFUSION EFFECTS

Let us first consider two resolution limits due to the diffusion effect, namely the minimum detectable phase related to

Figure 1 Bandwidth limited resolution $(\Delta r)_B$ in relation to the applied gradient G and data acquisition time T_{acq} . To obtain a high-resolution image in the order of 1–10 μm , it is necessary to have either a large gradient or long data acquisition times. Since excessively long data acquisition time is not advantageous due to the expected increase of the diffusion limited resolution, a large gradient strength is usually necessary. For this reason, NMR microscopy usually requires much larger gradient strengths than those employed in conventional whole body imaging

the random phase fluctuation and the phase dispersion related to the signal attenuation. In each case, our experimental model assumes free water molecules physically unbounded by impenetrable boundaries or walls. Following these two limits, a Monte Carlo (MC) simulation study of water molecules confined within boundaries or walls will be discussed as an alternative model for diffusion related resolution on the microscopic scale.

3.1 Resolution Limit as a Minimum Detectable Phase Difference due to Random Brownian Motion

According to the random walk model of the diffusion process developed by Carr and Purcell,¹² one-dimensional movement of the spin from an initial position x_0 due to the diffusion process is expressed as

$$\begin{aligned} x_i &= x_{i-1} + \alpha_1 \zeta \\ &= x_{i-2} + \alpha_{i-1} \zeta + \alpha_1 \zeta \\ &\vdots \\ &= x_0 + \zeta \sum_{j=1}^i \alpha_j \end{aligned} \quad (5)$$

where x_i is the position after a movement with reference to the previous position x_{i-1} with a discrete distance ζ , and α_i is a random variable which is either +1 or -1 with equal probability. In the case of imaging using a time varying gradient

field $G(t)$ along the x direction, the total accumulated phase ϕ_N after a given time ($t = N\epsilon$) can be expressed as

$$\begin{aligned} \phi_N &= \gamma \epsilon \sum_{k=1}^N (G_k x_k) \\ &= \gamma \epsilon \zeta \sum_{k=1}^N \left[G_k \left(\sum_{j=1}^N \alpha_j \right) \right] \\ &= \gamma \epsilon \zeta \sum_{k=1}^N \left[\alpha_k \left(\sum_{j=k}^N G_j \right) \right] \end{aligned} \quad (6)$$

where ϵ is a time interval for each movement, and G_k is the gradient field at $t = N\epsilon$, i.e. $G(t = N\epsilon)$.

If the initial time is set at the beginning of the imaging gradient, the initial-position-dependent phase $\phi = \gamma G x_0 t$ is deterministic, and can be retrieved by the FT. It is, therefore, excluded in equation (6) where only the random-phase terms are considered. From equation (6), assuming that the mean phase is zero, the variance of the phase fluctuation at $t = N\epsilon$ is given by

$$\sigma_\phi^2(t = N\epsilon) = E[\phi_N^2] = \gamma^2 \epsilon^2 \zeta^2 E \left\{ \left[\sum_{k=1}^N \alpha_k \left(\sum_{j=k}^N G_j \right) \right]^2 \right\} \quad (7)$$

where $E[\cdot]$ denotes the statistical expectation. Considering the fact that the α_k terms are the only stochastic terms, and α_m and α_n are mutually independent, i.e. $E(\alpha_m, \alpha_n) = 0$ for $m \neq n$, and $E(\alpha_m^2) = 1$ for all $m = 1, 2, \dots, N$, equation (7) can be rewritten as

$$\sigma_\phi^2(t = N\epsilon) = \gamma^2 \epsilon^2 \zeta^2 \sum_{k=1}^N \left(\sum_{j=k}^N G_j \right)^2 \quad (8a)$$

For a sufficiently small time interval ϵ , equation (8a) can be expressed in integral form as

$$\sigma_\phi^2(t = N\epsilon) = 2\gamma^2 D \int_0^t \left[\int_{t'}^t G(t'') dt'' \right]^2 dt' \quad (8b)$$

where the quantity $\zeta^2/2\epsilon$ is replaced by the diffusion coefficient D and ϵ by dt' and dt'' . Equation (8b) describes the diffusion related phase variance as a function of continuous time rather than at a specific time, such as the time relative to an echo forming point, etc. In order to apply equation (8b) to NMR microscopy, a basic pulse sequence is considered, i.e. the data acquisition is started immediately after the 90° rf pulse. In this case, i.e. $t' = 0$ and $t = T$ in equation (8b), the variance is given by

$$\sigma_\phi^2(t) = 2\gamma^2 D G^2 T^3 / 3 \quad (8c)$$

Using equation (3) and equation (8c), one obtains the diffusion limited resolution $(\Delta r)_D$ as

$$(\Delta r)_D = \sqrt{\frac{2}{3} D T_{acq}} \quad (9)$$

For example, in water with $D = 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, if an acquisition time of $T_{acq} = 1.5 \text{ ms}$ is used, then the diffusion related resolution limit is

$$(\Delta r)_D = \sqrt{\frac{2}{3}(10^{-5} \text{ cm}^2 \text{ s}^{-1})(1.5 \times 10^{-3} \text{ s})} = 1.0 \mu\text{m} \quad (10)$$

Figure 2 shows the diffusion dependent resolution limit as a function of diffusion coefficient D for several data acquisition periods ranging from 200 μs to 5.0 ms. As shown, with a given data acquisition time of $T_{\text{acq}} = 1.5 \text{ ms}$, the diffusion limited resolution is only 1 μm . Therefore, it appears that the diffusion limited resolution does not have a significant effect on the overall resolution of NMR microscopy. With a large diffusion coefficient (about $10^{-4} \text{ cm}^2 \text{ s}^{-1}$) and a long data acquisition time (about 5 ms), however, diffusion limited resolution, based purely on the minimum detectable phase criterion alone, could reach a resolution up to the order of 10 μm , a significant value in micrometer resolution NMR microscopy.

3.2 Resolution Limit as a Line-spread due to the Diffusion Dependent Signal Attenuation

As shown in the previous section, molecular diffusion results in a spin phase dispersion which eventually leads to signal attenuation. With a Gaussian distribution, the signal intensity can be expressed as

$$A(t) = A(0) \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi\sigma_\phi^2}} \exp\left[-\frac{\phi^2(t)}{2\sigma_\phi^2}\right] \cos \phi \, d\phi \quad (11)$$

where ϕ denotes the phase, $A(0)$ is the initial amplitude, and σ_ϕ is the standard deviation given in equation (8b). Equation (11) can be further simplified to

$$A(t) = A(0) \exp[-\sigma_\phi^2(t)/2] \quad (12)$$

If we substitute the variance given in equation (8b) into equation (12), we obtain

Figure 2 Diffusion limited resolution $(\Delta r)_D$ based on the minimum detectable phase difference as a function of the diffusion coefficient D , with the data acquisition time T_{acq} as a parameter. It can be seen that the resolution degradation due purely to the minimum detectable phase difference is relatively small in water-like molecules

$$A(t) = A(0) \exp\left\{-\gamma^2 D \int_0^t \left[\int_{t'}^t G(t'') \, dt''\right]^2 dt'\right\} \quad (13)$$

Alternatively, equation (13) can also be written as

$$\ln[A(t)/A(0)] = -\gamma^2 D \int_0^t \left[\int_{t'}^t G(t'') \, dt''\right]^2 dt' \quad (14)$$

It is worth noting that, for the special case of echo formation, equation (13) becomes identical to the formula derived previously.¹⁷ For example, if an echo is formed at time $t = TE$, $\int_0^{TE} G(t') \, dt' = 0$. The term in brackets in equation (14) can then be written as

$$\begin{aligned} \int_{t'}^{TE} G(t'') \, dt'' &= \int_{t'}^0 G(t'') \, dt'' + \int_0^{TE} G(t'') \, dt'' \\ &= -\int_0^{t'} G(t'') \, dt'' \end{aligned} \quad (15)$$

Equation (15) is identical to the equation given by Karlicek and Lowe.¹⁷

We also find that the echo signal amplitude derived by Stejskal and Tanner¹⁶ in the pulsed gradient experiment is consistent with equation (13), as it should be. The time dependent signal attenuation will then lead to image degradation as a part of the diffusion phenomena, since signal amplitude attenuation during the data acquisition period will lead to line broadening, similar to the Lorentzian broadening due to T_2 decay.

By numerical FT of the diffusion affected signal given in equation (13), the line spread function $P(x)$ can be derived:

$$P(x) = [1/A(0)] \int_{-\infty}^{\infty} A(t) \exp(-i2\pi xt) \, dt \quad (16)$$

In order to examine the line broadening effect due to the time varying signal attenuation during the data acquisition period, the full width at half maximum (fwhm) of the line spread functions for FIDs with several different diffusion coefficients were calculated; the results are given in Table 1. Although the resolution given by equation (16) is not an intrinsic resolution compared with the diffusion-limited resolution based on the minimum detectable phase, it is nevertheless an important practical measure of the resolution in NMR microscopic imaging.

3.3 Monte Carlo Simulations of Diffusion Effects and Resolution Anomalies in the Case of Water Molecules Confined by Boundaries or Walls

In the two previous sections, the basic principles and effects of diffusion in free space on the NMR signal were discussed. However, in many practical cases, such as biological samples, the nuclei in a sample during NMR imaging experiments do not diffuse freely in a finite and limited space; this generates substantial anomalies in resolution and image formation. In general, the purpose of NMR imaging is to distinguish the domains where imaging parameters, such as spin density (ρ) and physical or chemical properties (T_1 , T_2 , χ) of the nuclei, are different, provided that the nuclei belonging to one domain barely move to neighboring domains, at least during the data acquisition time. That is, there are impenetrable boundaries between the domains within an image or object. Therefore, the

Table 1 The fwhm (μm) of the line spread functions as a function of the diffusion coefficient for three different gradient field strengths in NMR microscopy^a

G (mT m^{-1})	0	D ($\text{cm}^2 \text{s}^{-1}$)		
		10^{-6}	10^{-5}	10^{-4}
0.4	4.8	4.9	5.1	7.5
0.2	4.8	4.9	5.3	10.1
0.1	4.8	4.9	5.8	14.0

^aThe resolution given by the reciprocal of the bandwidth was set at 4 μm . The line spread functions are given in fwhm (μm) and were obtained by FT of the FID data.

general analysis based on free diffusion may not be a suitable model for NMR microscopy of small objects or regions confined by boundaries, since in this case diffusion is no longer free diffusion. However, in principle, resolution is only important near the boundary, because inside a homogeneous domain far from boundaries it is not necessary to distinguish two neighboring pixels and resolution does not matter.

Lauterbur et al.¹⁸ and Pütz et al.¹⁹ have reported how these impenetrable boundaries or walls can distort or even enhance images at the microscopic scale in MRI. Image intensity is enhanced near the boundaries when the diffusion coefficient is modest, and increases or focuses around the center of the domain when the diffusion coefficient becomes large.¹⁹ Pütz derived an expression of the lineshape function for the case of diffusion in a bounded case by solving the diffusion Bloch equation¹⁹ numerically. The same result can be obtained by means of a Monte Carlo simulation based on the random walk molecular diffusion process. The Monte Carlo simulation could possibly provide better insight into the problem, since it can simulate the random walk problem more closely than can the analytical approach. In the following, Monte Carlo approaches to the problem are described. We have assumed that the molecular self-diffusion stems from microscopic scattering between molecules. The direction and speed of molecules after each scattering are assumed to be random, as are the intervals and distances between movements and scatterings (Figure 3). In this simulation study, however, this random process was simulated by the random walk model, where each direction of the scattered molecules is determined randomly while the interval and distance are fixed at their average values. In the following Monte Carlo simulation, based on this random walk model, both unrestricted free molecular motion and molecular motion that is restricted in one dimension are described. It is also assumed that the direction of each Monte Carlo step is chosen as either left or right, and the phase of each spin in a linear magnetic gradient field is traced as a function of time. The FID signal is then obtained at the end by vectorially summing the phases. The FID obtained in this way is Fourier transformed and the lineshape function is obtained. The phase of a spin in a linear gradient field at time $N\Delta t$ is calculated as

$$\phi(N\Delta t) = \sum_{i=1}^N \gamma G x_i \Delta t \quad (17)$$

where G is the gradient, Δt is the time interval between each Monte Carlo step, and x_i is the particle position at time $i\Delta t$.

The position or spatial distribution of the spins by the random walk follows the binomial distribution and approaches the

Figure 3 Illustration of the random Brownian motion and Monte Carlo (MC) steps assumed in the simulation study. The data sampling or updating time ΔT is assumed to be 10 times the individual spin movement time Δt . The drawing on the right is an example of the expanded details of a local Brownian motion shown on the left

normal distribution in the limit when the number of trials is large. The approximation is good if the number of trials is greater than 10, when the probabilities of two events are the same.²⁰ Since the diffusion equation predicts a normal distribution when the initial density distribution has the form of a delta function, the number of the random walk steps was chosen always to be greater than 10 in order to match the macroscopic prediction. Data acquisition was started immediately after the magnetic gradient field was applied, i.e. the FID was detected and the phase value was updated at every ΔT interval. Note that here ΔT is assumed to be $10 \Delta t$.

Figures 4(a) and Figure 4(b) show the spatial distributions of the spins for the cases where molecules are unbounded (molecular diffusions in free space) and bounded by a wall to the right, respectively, after 400 Monte Carlo steps. In Figure 4(b), the spins were distributed over an infinitesimally thin slab at position $x = 0$ at $t = 0$. Spins are randomly moved one step to the left or right with equal probability at every Monte Carlo step, except for those near the wall in the case of bounded diffusion. As can be seen, the profile of the spatial distribution of the spins which diffuse freely in an infinite space are very close to the normal Gaussian distribution. In the case of bounded diffusion, however, those spins that reached the wall moved one step back with a probability of -1 . The spin density near the wall, therefore, increased as shown in Figure 4(b). In other words, the spatial or position distribution in the presence of the wall is expected to have a form which has a similar distribution function to that for the free diffusion on the left side of the wall ($x < 0$), but on the right side of the wall ($x > 0$) the distribution function is of an asymmetrical form, as shown in Figure 4(b). This is because those spins supposed to be outside the wall are now symmetrically folded over to the inside.

The important factor for imaging, however, is not the position but the phase distribution of these spins, since the spin phase distribution, not the spin position, determines the image. It is also important to note that the linear gradient is added in MRI, which is space variant, and therefore gives a different amount of phase variation along the x direction, i.e. the phase value increases proportionally as the position moves to either the right or the left. Figure 5 shows the position and phase distributions for comparison. The phase distribution profile in free diffusion is Gaussian, as for the case of the position distribution. However, in the case of bounded diffusion it is

Figure 4 Spreads of the unbounded (free) and bounded spins located at $x = 0$ (with $t = 0$) at $t > 0$. At $t = 400\Delta t$, the typical spin position spread follows a Gaussian distribution in the free diffusion case (a), but in the bounded or restricted case (b) an asymmetrical Gaussian distribution is seen

different [Figure 5(b)] and requires further explanation. In MRI, the differences between the position distribution and phase distribution in the case of bounded spins are due to the fact that it is not the spin positions but the phases that are recorded, and thereby the phase increases as time goes on. The final distribution of the phase, therefore, becomes distorted, as shown in Figure 5(b).

To observe the bounded spin effect in an imaging situation, both the spatial and phase distributions are measured for spins that are distributed uniformly in a box. First, the spatial distributions should be uniform and time invariant. The phase distributions, however, would be different. To observe this effect near the boundary of an image, a Monte Carlo simulation was performed using equation (17). Then the phase distribution of the nuclear spins distributed uniformly in a one-dimensional box was recorded. The size of the box was $20\ \mu\text{m}$ divided into 200 pixels with a linearly changing magnetic field which becomes zero at the center of the box (Figure 6). Similarly to the case of the delta function distribution shown in Figure 5(b), the resulting phase distribution, approaching the walls or boundaries, is different from the position distribution. At the boundaries, the number of spins that should be at $\phi = \phi_{\text{max}}$ decreases substantially, and instead are recorded at values larger than and smaller than ϕ_{max} [see Figure 5(b)]. This means that the spin phase distribution in the reverse direction, that is towards the center of the wall, would increase and show a peak, which would then again decrease to a normal value approaching the center. On the outside of the walls, i.e. $\phi \geq$

ϕ_{max} , there could be a small leakage, as shown in Figure 5(b). Except near the boundaries, the phase distribution does not change even in the presence of diffusion, because the number of spins of a given phase, other than those near the boundaries, does not change, as discussed previously, although the spin positions change during a data acquisition period. Therefore, the central part of the image is not distorted and the resolution is not affected for the spins well inside the boundaries.

Based on the phase distributions obtained, image reconstruction was performed by FT, the results of which are shown in Figure 7. The figure shows only the right-hand halves of the final reconstructed images obtained by FT of the FID signal. The dashed line is the image with no diffusion. These images were obtained from 256 FID data points and each FID is obtained by summing the phases of all the spins (10^6) at every 10 Monte Carlo steps up to 2560 steps. Since the average collision time of water molecules interacting with biological macroscopic molecules is about $10^{-6}\ \text{s}$,²¹ we set one Monte

Figure 5 (a) The spin position distribution, and (b) the phase distribution of the free (---) and bounded (—) spins originated from $x = 0$ (at $t = 0$) observed at time $t = 400\Delta t$. (a) The position spread of the bounded spins is limited at the wall, while the unbounded spins follow a normal Gaussian distribution. (b) Although the position distribution and phase distribution look similar, there is a difference. In the case of the phase distribution, at $\phi = \phi_{\text{max}}$, the maximum phase of the bounded spins is normalized by the phase value at the boundary where the gradient field is strongest. The number of spins having the maximum phase is less than half the peak value, suggesting that there will be less intensity in the reconstructed image based on the phase values

Figure 6 Modeling of the Monte Carlo simulation study of the diffusion process in a one-dimensional box. Uniformly distributed water molecules in a box restricted over a $20\ \mu\text{m}$ (in the x direction) length was assumed. Each pixel is then assumed to be $0.1\ \mu\text{m}$ long in the x direction, with 5000 spins (or particles) in each pixel. The applied gradient G , total data acquisition time T , data sampling time interval ΔT , each Monte Carlo step Δt , range of values of the diffusion coefficient D , bandwidth limited resolution $(\Delta r)_B$, and number of pixels in the box n are indicated on the figure. The total number of spins or particles used for the simulation was 10^6 .

Carlo step (Δt) as $1\ \mu\text{s}$ in order to simulate the imaging of a biological cell, and the sampling or data updating interval (ΔT) was set at $10\ \mu\text{s}$. The total data acquisition time is then $2.56\ \text{ms}$ for 256 sampled data. Given this step time (Δt), the assignment of $0.1\ \mu\text{m}$ for the distance moved during each step gives a diffusion coefficient close to those of the biological samples described below. The simulated length of the object, and therefore the image, was assumed to be $20\ \mu\text{m}$, with the size of each pixel being $0.1\ \mu\text{m}$. The right-hand half of the image ($10\ \mu\text{m}$) is shown in Figure 7. Since the variation in position in the binomial distribution σ^2 is $N\Delta x^2/4$, where N is the total num-

Figure 7 Reconstructed image patterns based on the phase distributions obtained by Monte Carlo simulation for various values of diffusion coefficient D . Some edge enhancement and image deformation are evident, but the edge enhancement effect is visible only within a few micrometers, even with a diffusion coefficient as large as $D = 2.0 \times 10^{-4}\ \text{cm}^2\ \text{s}^{-1}$. For normal water molecules (e.g. $D = 1.25 \times 10^{-5}\ \text{cm}^2\ \text{s}^{-1}$), therefore, deformation or contraction of the image size and enhancement effect may not be readily visible at the resolution of NMR microscopes currently available.

ber of trials and the variation in position at time t is given by $(2Dt)^{1/2}$ in a diffusion process, one obtains the relationship $D = N\Delta x^2/8T$ when the total number of trials N is defined as the total number of Monte Carlo steps ($N = 2560$) and the time T is the total data acquisition time ($T = 2.56\ \text{ms}$). From these data, one obtains a diffusion coefficient of $D = 1.25 \times 10^{-5}\ \text{cm}^2\ \text{s}^{-1}$. The third curve shown in Figure 7 corresponds to the case of this diffusion coefficient, which is close to the diffusion coefficient of free water. In the same figure, the first curve from the right has a diffusion coefficient 16 times smaller than that of the third curve. The rest of the curves have diffusion coefficients that are 4 times larger than the one to the left. The magnetic gradient field was set to make the phase at the right end increase by 1 rad at every sampling or updating interval ΔT . This condition corresponds to a gradient field of $3.78\ \text{mT}\ \text{m}^{-1}$ and a bandwidth limited resolution of $0.25\ \mu\text{m}$. The overall simulation conditions are depicted in Figure 6.

Although small signal penetration or leakage exists in the immediate vicinity of the boundary, the values seen are small and of no significant consequence. Inside the domain or box the signal intensities show peaks or overshoots in the immediate vicinity of the boundary, as discussed earlier. In addition, each curve settles to the normal value as it approaches the center. Overall, those overshoots or anomalies in the signal intensity of the reconstructed image at the boundary appear as an image resolution enhancement near the boundaries. These kinds of resolution anomalies are the unexpected result of the conventional idea that the image would be blurred by diffusion effects, regardless of the presence of boundaries or other barriers. At the same time, this boundary enhancement effect will appear as a signal void (or a dark region) between the two neighboring domains if these are adjacent to each other, thereby making a clearer boundary. An undesirable part of the effect, however, is the image distortion, e.g. a domain or an image contracts with increasing diffusion coefficient and the distances of the peaks from the boundary also tend to increase as the diffusion coefficient increases (see Figure 7). Although these peakings and image contractions appear significant in this example, the effect may not be readily observable in current in vivo NMR microscopy of biological samples, where the resolution is at best, in the range $4\text{--}10\ \mu\text{m}$, with diffusion coefficients in the range $1\text{--}2 \times 10^{-5}\ \text{cm}^2\ \text{s}^{-1}$.^{1,5}

Contrast Agents in Magnetic Resonance: Operating Mechanisms

Robert N. Muller

University of Mons Hainaut, Mons, Belgium

1 THE MR IMAGE AND ITS CONTRAST

For the creation of a clinical magnetic resonance image, the electromagnetic signal emitted by each volume element (*voxel*) of the body is spatially identified by the application of magnetic field gradients. It is subsequently registered at its proper location in the two- or three-dimensional array of the digital picture. The brightness of any of the picture elements (*pixels*) is directly related to the intensity of the NMR signal broadcasted by the corresponding voxel (see *Image Formation Methods*). Consequently, intensity differences between adjacent voxels determine the image contrast.¹ At this point, it is worth remembering that MRI differs fundamentally from X-ray computerized tomography since it maps a signal emitted by each voxel while the latter imaging modality reflects an attenuation of the beam of ionizing radiation passing through the body of a patient.

Inherent contrast of a magnetic resonance image can be manipulated to a much larger extent than in any other technique. This *natural* contrast enhancement is achieved by modifying the instrumental or *extrinsic* factors of the imaging procedure such as the type and the timing parameters of the pulse sequence. This strategy can highlight the influence of certain *intrinsic* parameters such as the local concentration of nuclei (also called ρ , the spin density), their relaxation parameters (T_1 , T_2 , T_2^* , $T_1\rho$), the relative bulk magnetic susceptibility, bulk flow of cerebrospinal fluid (CSF) or blood, or the molecular self-diffusion coefficient.

In common imaging sequences, signal intensity is proportional to ρ and spin-spin relaxation (T_2 as well as T_2^*) and inversely related to the spin-lattice relaxation, T_1 . In other words, main contrast influencing factors in MRI are proton density and the two relaxation times T_1 and T_2 .

Despite the outstanding contrast flexibility of MRI, some diagnostic questions have prompted the need for exogenous contrast material. These pharmaceuticals aim at enhancing the contrast between normal and diseased tissues or at providing functional information regarding the state of an organ by dynamically modifying the intrinsic parameters of the tissues. This can be done by either increasing signal intensity (positive agents) or by decreasing signal intensity (negative agents). The straightforward target in the development of such MR contrast agents is alteration of proton density and of relaxation times.

2 MODIFICATION OF PROTON DENSITY

Possible contrast agents which can modify the water content of tissues are diuretics, hormones, and alcohol. Because of their limited contrast changes and their manifold side-effects, these drugs are not used for clinical applications. A more feasible approach is to displace water in the region of interest.

Among the compounds applied for this purpose is perfluorooctyl bromide (PFOB) which is used as a negative oral contrast agent.² By replacing the watery content of the intestines, PFOB darkens the bowels. For the same purpose, barium sulfate and clays have been proposed; they partly replace water in the gastrointestinal tract and also modify its nuclear relaxation kinetics by offering large adsorption surfaces. Relaxation parameters may indeed be influenced by an alteration of molecular dynamics but are more efficiently modified by intensifying dipole-dipole magnetic interactions.

3 MODIFICATION OF NUCLEAR RELAXATION RATES

Theory predicts that an excited proton isolated in the vacuum and submitted to a static magnetic field of 1.5 T would require more than 10^{16} years to return spontaneously to its stable Zeeman state. On the other hand, if another magnetic center, such as a proton, is fluctuating nearby, the relaxation process takes place in a timescale of a second. This is the situation encountered in pure liquid water or in tissues where the longitudinal relaxation times T_1 are around 4 s or fractions of a second, respectively. If an electron, which is 658 times more magnetic than a proton, were to be located in the close vicinity of the hydrogen nucleus, the dipole-dipole (electron-nucleus) interaction, which increases by the square of the magnetic moments, would lead to a relaxation process taking place in a few microseconds.

Assuming a concentration of 1 mM of electrons for a hypothetical aqueous solution, its global relaxation time would be around 0.5 s. MR relaxation agents should thus be chemical structures rich in unpaired electrons, i.e. be *paramagnetic*. Potential candidates are organic stable free radicals, molecular oxygen, ions, and complexes of transition metals (Fe^{2+} , Fe^{3+} , Mn^{2+} , Mn^{3+} , etc.) or of lanthanides (Gd^{3+} , Ho^{3+} , Dy^{3+} , etc.). Nanocrystals of ferrites which are known to exhibit extremely high magnetic moments at high magnetic fields are also drawing interest. These latter compounds belong to the family of *superparamagnetic* materials.

Such contrast agents catalyzing the relaxation processes are sometimes called *magnetopharmaceuticals*. Here again, a clear distinction between X-ray and MRI has to be made. In the former technique, the contrast media are themselves visualized since they scatter or block the incident beam, while in MRI the contrast enhancing material is indirectly observed through its action on the proton relaxation of water in tissue. For this reason, these materials should be called *contrast agents* rather than *contrast media*, the latter term being reserved for directly visible substances.

4 RELAXIVITY

The efficiency of relaxation agents with respect to the longitudinal (T_1) or transverse (T_2) relaxation processes is usually quantified in terms of their *relaxivity* r_i ($i = 1$ or 2), the increment brought to the solvent (water) protons' relaxation rate by 1 mmol L^{-1} of the paramagnetic center:

$$R_{i(\text{obs})} = \frac{1}{T_{i(\text{obs})}} = \frac{1}{T_{i(\text{diam})}} + r_i C; \quad i = 1 \text{ or } 2 \quad (1)$$

where $R_{i(\text{obs})}$ and $1/T_{i(\text{obs})}$ are the global relaxation rate of the aqueous system (s^{-1}); $T_{i(\text{diam})}$ is the relaxation time of the system before addition of the contrast agent (s); C is the concentration of the paramagnetic center (mmol L^{-1}); and r_i is the relaxivity ($\text{s}^{-1} \text{ mmol}^{-1} \text{ L}$).

5 RELAXATION MECHANISMS

5.1 Paramagnetic Relaxation

Quantitative models describing dipolar interaction have been developed to express mathematically the relaxivity of the paramagnetic centers. The complete picture is given by a juxtaposition of the two mechanisms depicted in Figures 1 and 2, which are called the 'innersphere' and the 'outersphere' mechanisms, respectively.³

5.1.1 Innersphere Mechanism

A paramagnetic moiety, characterized by an electronic spin S ($7/2$ for Gd^{3+} , $5/2$ for Mn^{2+} , etc.) is surrounded by n water molecules lying at a distance r in its first coordination sphere (Figure 1). From a dynamical point of view, it has to be taken into account that the magnetic interaction fluctuates, because:

Figure 1 Schematic representation of the innersphere relaxation mechanism induced by a paramagnetic center on temporarily coordinated water molecules

Figure 2 Schematic representation of the outersphere relaxation mechanism originating from the interaction between a paramagnetic center and water molecules diffusing at close vicinity

1. The temporarily coordinated molecules are exchanging with the bulk water (residence time τ_M).
2. The whole complex is experiencing Brownian motion (rotational correlation time τ_R).
3. The electrons are subject to their own relaxation processes, i.e. flip-flop exchange between their Zeeman levels (electronic relaxation times τ_{S1} and τ_{S2}).

The efficiency of the energy transfer between the excited nuclei and the lattice depends critically on the timescale of this modulation.

The relaxation times of the water protons located in the first coordination sphere of the metal are T_{1M} and T_{2M} . Assuming a propagation of the effect due to the exchange with the bulk (τ_M) the net contribution of this 'diluted' innersphere mechanism to the global relaxation rate will be:

$$R_{1,2 \text{ inner}} = \frac{1}{T_{1,2 \text{ inner}}} = \frac{P_M n}{T_{1,2M} + \tau_M} \quad (2)$$

with $P_M \ll 1$, where P_M is the mole fraction of the paramagnetic center; n is the number of water molecules bound in the first coordination sphere of the metal, and τ_M is the residence time of the water bound to the paramagnetic center.

This equation, which is always correct for R_1 , is more complex for R_2 if τ_M becomes longer than $1 \mu\text{s}$. On the other hand, an exchange time of water (τ_M) of the order of or longer than T_{1M} , the relaxation time in the first coordination sphere, will drastically reduce the relaxivity.

Calculation of T_{1M} or of $(1/T_{1M})$ is based on a model which includes the amplitude of the magnetic interaction, its temporal modulation (τ_R , τ_M , τ_{Si}) and the effect of the intensity of the external static magnetic field B_0 .

The complete set of simplified equations for $1/T_{1M}$ [equation (3a)] and $1/T_{2M}$ [equation (3b)] are known as the Solomon–Bloembergen–Morgan relations:

$$\frac{1}{T_{1M}} = \frac{B}{r^6} \left[\frac{7\tau_{c2}}{1 + (\omega_S\tau_{c2})^2} + \frac{3\tau_{c1}}{1 + (\omega_I\tau_{c1})^2} \right] + \frac{2A^2S(S+1)}{3\hbar^2} \left[\frac{\tau'_{c2}}{1 + (\omega_S\tau'_{c2})^2} \right] \quad (3a)$$

$$\frac{1}{T_{2M}} = \frac{B}{r^6} \left[\frac{6.5\tau_{c2}}{1 + (\omega_S\tau_{c2})^2} + \frac{1.5\tau_{c1}}{1 + (\omega_I\tau_{c1})^2} + 2\tau_{c1} \right] + \frac{A^2S(S+1)}{3\hbar^2} \left[\frac{\tau'_{c2}}{1 + (\omega_S\tau'_{c2})^2} + \tau'_{c1} \right] \quad (3b)$$

where: $B = 2\gamma_I^2\gamma_S^2\hbar^2S(S+1)/15$; $A/\hbar$ is a constant characterizing the scalar interaction (v.i.); and

$$\frac{1}{\tau_{ci}} = \frac{1}{\tau_R} + \frac{1}{\tau_M} + \frac{1}{\tau_{Si}} \quad (3c)$$

$$\frac{1}{\tau'_{ci}} = \frac{1}{\tau_M} + \frac{1}{\tau_{Si}} \quad (3d)$$

Equations (3a) and (3b) show a clear field dependence of the relaxivities through the Larmor frequencies of the electron (ω_S) and the proton (ω_I), respectively. The additional field dependence of τ_{Si} , is less obvious, but also influences the relaxivities.

Except for aquo ions of some transition metals, like manganese, which delocalize their electronic orbitals on the water protons, the second term of these equations (representing the so-called *scalar term*) has to be neglected. This is also the case for lanthanide complexes relaxing water protons.

At low field or for fast molecular motion conditions ($\omega_S\tau_{ci}$, $\omega_I\tau_{ci} \ll 1$), $1/T_{1M} = 1/T_{2M}$. Unless a scalar interaction exists, this relationship is maintained as long as the condition $\omega_I\tau_{ci} \ll 1$ is fulfilled. When the product $\omega_I\tau_{ci}$ becomes larger than 1, $1/T_{1M}$ drops progressively to 0, while $1/T_{2M}$ maintains a significant value, usually referred to as the *secular term*. This divergent behavior leads to the large r_2/r_1 observed for macromolecular paramagnetic systems.

5.1.2 Outersphere Mechanism

Water molecules moving freely in the vicinity of the paramagnetic center can also interact with the electronic spin. This phenomenon, which does not require any binding between the two species, is governed by the relative motion of the molecules and their distance of closest approach (Figure 2). The time modulation of the magnetic interaction is characterized by a diffusion correlation time τ_D :

$$\tau_D = d^2/(D_I + D_S) \quad (4)$$

where d is the distance of closest approach, and D_I and D_S are the molecular self-diffusion coefficients of water and the magnetic center, respectively.

The equations describing the outersphere relaxation mechanism have some similarities with those of the innersphere relaxation, i.e. a strong field dependence, equal r_1 and r_2 at low field, and an increasing r_2/r_1 ratio when $\omega_I\tau_D$ becomes larger than 1. Here again, high field conditions and long correlation times (τ_D), such as those encountered with large magnetic bodies like magnetic particles, may induce such a

situation where the transverse relaxivity is faster than the longitudinal one (see Sections 5.1.1 and 5.2).

From the foregoing, the global relaxation rate of a paramagnetic aqueous solution has to be written as:

$$R_{1,2 \text{ obs}} = \frac{1}{T_{1,2 \text{ obs}}} = \frac{1}{T_{1,2 \text{ diam}}} + \frac{1}{T_{1,2 \text{ inner}}} + \frac{1}{T_{1,2 \text{ outer}}} \quad (5)$$

5.1.3 Nuclear Magnetic Relaxation Dispersion Profiles and Field Cycling Relaxometry

The influence of each parameter contained in the rather complex equations expressing the relaxivities is better visualized when r_1 and r_2 are represented as functions of the static magnetic field (or of the proton Larmor frequency). These curves are called nuclear magnetic relaxation dispersion (NMRD) profiles. Figure 3 shows, for instance, the effect of the rotational correlation time τ_R on the r_1 innersphere for a system which could be made of a gadolinium(III) ion complexed by organic chelates of increasing molecular size.

In addition, the experimental NMRD profiles are of paramount importance, if not mandatory, to understand, improve, and quantify the relaxation phenomena. They are conveniently recorded over a wide range of fields, typically from a few tens of a millitesla up to 1 T and more, on a special instrument, the field-cycling relaxometer developed from the original idea of Redfield.^{4,5} Data are subsequently fitted with the relevant theoretical models mentioned above.

Complementary information can be obtained by alternative techniques like luminescence (number of coordinated water molecules, n), oxygen-17 nuclear relaxation (water residence time in the first coordination sphere τ_M), carbon-13 nuclear relaxation (rotational correlation time τ_R), and crystallography (distance between water protons and the metal, r).

Figure 3 Simulated longitudinal innersphere relaxivity (r_1) profiles of gadolinium chelates of increasing molecular size. The peculiar evolution in the high field range is due to the involvement of the electronic relaxation in the global modulation time τ_c for larger molecular weight [see equation (3c)]

5.2 Superparamagnetic Relaxation

Small crystals (<20 nm) of magnetite (Fe_3O_4) and of other ferrites are known to exhibit extremely high magnetic moments due to a cooperative alignment of the electronic spins of the individual paramagnetic ions they contain.^{6,7} These nanoparticulate materials do not retain any remanent bulk magnetization after having been exposed to a strong magnetic field. Although they are always fully magnetized, these particles have their magnetic moment flipping rapidly and randomly between some preferred directions of the crystal. This means that at very low external magnetic field the net bulk magnetization of these particulate materials tends to null, while the mean squared modulus of their individual magnetization vector measured along the direction of the external field is one-third of the value measured at high field where all the moments are locked, yielding the saturation magnetization. In addition to the external field, the magnetic moment of the particle experiences another constraint caused by the crystal anisotropy. This effect, which presents some analogies with the zero-field splitting well known in paramagnetic systems, causes an attenuation of a low-field dispersion that can totally disappear, as in Figure 4 (for a complete description of the relaxation induced by superparamagnetic particles see, for instance Roch et al.⁸).

Relaxation induced by such systems is obviously of the outersphere type. Considering the size of these grains ($R \approx 10$ nm in Figure 2), the time during which the traveling water protons 'feel' the magnetic heterogeneity is relatively long. In this situation one can predict that the effect on the proton transverse relaxation will be by far more important than on the longitudinal one (see Section 5.1.2). These contrast agents are referred to as T_2 relaxers. However, it should not be over-

looked that they can nevertheless present impressive r_1 relaxivities.

Classical outersphere theory is not applicable to these systems which, as mentioned above, are characterized by unusual sizes and magnetic properties. In recent studies,^{9,10} a new model has been proposed (Figure 4) which adequately fits the NMRD experimental data of longitudinal relaxivity and allows predictions regarding the influence of various parameters (size, saturation magnetization, etc.).

Transverse relaxivity can be analytically predicted for ideally dispersed crystals of rather small size (ca. 20 nm for magnetite). The influence of larger grains or clusters on T_2 and T_2^* , however, has to be estimated by computer simulations which evaluate the dephasing of spins diffusing in a three-dimensional space containing the randomly distributed magnetic centers.^{11,12}

5.3 Susceptibility-Induced Relaxation

The mechanisms presented so far involve the acceleration of the relaxation processes due to short range interactions between the water protons and the individual magnetic centers. The processes thus influence the water molecules that are permanently or temporarily located in their compartment. Another type of relaxation enhancement which is strictly limited to the transverse evolution of the nuclear magnetization can be induced by microscopic magnetic field gradients created by susceptibility differences between compartments (see *Susceptibility and Diffusion Effects in NMR Microscopy* and *Susceptibility Effects in Whole Body Experiments*). The bulk magnetic susceptibility of the intravascular space is for instance increased by a high concentration of paramagnetic or superparamagnetic compounds.

Because of the molecular diffusion of water through the transcompartmental magnetic field heterogeneities, the apparent transverse relaxation time T_2^* will be shortened. This phenomenon will be maximal in gradient echo imaging sequences which do not contain spin refocusing rf pulses able to minimize this irreversible loss of phase coherence. Pure susceptibility effects are only achievable with magnetic materials exhibiting negligible r_1 . Otherwise antagonistic influences will develop between the inner and the outer compartments. In the former a signal increase could be expected, while in the latter the T_2^* would lead to a loss of intensity.

Among such susceptibility-only agents are those paramagnetic ions and complexes which have a very short electronic relaxation time τ_s , e.g. dysprosium.

Figure 4 The r_1 and r_2 NMRD profiles of an aqueous colloidal suspension of superparamagnetic iron oxide (Fe_3O_4 , crystal diameter 10.8 nm, particle diameter ca. 120 nm, specific magnetization 49 emu g^{-1}). Best fits of the experimental data according to the model described by Roch and Muller⁸ (parameters of the best fit: diameter 12.8 nm, specific magnetization 41 emu g^{-1} , ca. 30 crystals per particle). Neither the classical outersphere theory (.....) nor its variation assuming no bulk magnetization of the particles suspension at zero field⁹ (---) give satisfactory fits. Note that, as expected for such large magnetic centers, the transverse relaxivity r_2 (○) is much higher than r_1 (●) in the usual imaging field range

6 CLINICAL CONTRAST AGENTS

6.1 Relaxation Agents

6.1.1 Paramagnetic Complexes

Mn^{2+} was proposed very early on by Lauterbur et al.¹³ as the first in vivo relaxation agent. However, this ion, as with the other potentially efficient paramagnetic aquo ions (Gd^{3+} , Mn^{3+} , etc.) is rather toxic and cannot be used as such. Coordination chemistry offers elegant ways to prepare compounds made of paramagnetic ions locked in organic molecules, which are far less toxic than the free ion or even the free organic ligand.

Figure 5 Molecular structures of some open chain (1, 2) and macrocyclic (3, 4) chelates of the Gd^{3+}

Indeed, when the ion and ligand are bound together in a supra-molecular complex, neither is able to react *in vivo* and thus the ion does not replace important physiological ions such as calcium, and the ligand does not trap some other ion such as zinc.

The gadolinium ion (Gd^{3+}) has been chosen as the active center for the first generation of commercial complexes (Figure 5) because of its favorable physicochemical properties: seven unpaired electrons ($S = 7/2$), long electronic relaxation time (τ_{S1} , τ_{S2}), and nine coordination sites. From the point of view of relaxivity, structures which accept only one water molecule at a close distance to the gadolinium are obviously less efficient than the bare aquo ion. In spite of this, and due to their large size and an efficient outersphere relaxation mechanism, all of these compounds show relaxivities of around $4 \text{ s}^{-1} \text{ mmol}^{-1} \text{ L}$ at 0.5 T .

As for these small complexes, $\omega_1 \tau_{ci}$ much smaller than 1 (see Sections 5.1.1 and 5.1.2), the relaxivities r_1 and r_2 are almost equal. In other words, these contrast agents bring the same *absolute* rate increment to both R_1 and R_2 relaxation rates of tissues. However, since the transverse relaxation rates of tissues are larger than their R_1 the *relative* contribution these compounds add to the latter mechanism (at least for moderate concentrations) is predominant (see *Relaxometry of Tissue*, *Relaxation Measurements in Imaging Studies*, and *Relaxation Measurements in Whole Body MRI: Clinical Utility*). These magnetopharmaceuticals act as positive agents and are called T_1 agents. At present, the typical clinical dose is 0.1 mmol kg^{-1} body weight. For an adult, this corresponds to an injected volume of around 15 mL , considering that the concentration of the usual formulation is 0.5 mol L^{-1} .

The chemical stability of these compounds is very high as their dissociation constants in water at 37°C and $\text{pH } 7$ are lower than 10^{-16} . In other words, less than one molecule of the complex of around 100 million is dissociated.

As mentioned above, the active center of the paramagnetic complexes is an ion which is electrically charged. Sequestration of the triple-positive charge of the gadolinium ion is achieved in part by electrostatic interactions with the negatively charged carboxylate groups ($\text{O}=\text{C}-\text{O}^-$). As shown in Figure 5, the diethylenetriaminepentaacetic acid (DTPA) chelate offers more groups than necessary, since five negative charges are open to compensate for the positive charge carried by gadolinium. Gd-DTPA thus has two negative charges in excess, Gd-DOTA has

one, and Gd(HPDOTA) and Gd-DTPA-bis(methyl)amide (Gd-DTPA-BMA) are neutral. The last two compounds are thus called *nonionic* with respect to the former ones which belong to the class of *ionic* contrast agents.

Any negative charge in excess has to be neutralized by a counterion. The ammonium group (NH_3^+) of meglumine (methylglucamine), an organic molecule, has been chosen for this task. Gd-DTPA has thus to be considered as being composed of three molecules (i.e. the complex and two meglumine molecules), Gd-DOTA of two, while Gd-HPDO3A and Gd-DTPA-BMA are composed of only one molecule, the complex itself. For the same 0.5 mol L^{-1} concentration of gadolinium, the osmolarity of the latter compounds will be $0.65 \text{ osmol L}^{-1}$ which is half the osmolarity of Gd-DOTA and one third that of Gd-DTPA.

All these contrast agents are nonspecific and, owing to their low molecular weight and hydrophilicity, freely diffuse after intravenous injection from the intravascular into the extravascular and extracellular space. In the brain, while they do not cross the intact blood–brain barrier, they do enhance lesions with blood–brain barrier disruption or absent blood–brain barrier. The enhancement is also dependent on vascularization of damaged regions as well as on the tissue content of lesions.

The design of blood pool agents, potentially useful for MR angiography, is based on the synthesis of systems with a long life in the blood stream, while the development of hepatobiliary and tumor-seeking compounds requires appropriate knowledge of the mechanisms of internalization and of interactions with receptors. Among those specific agents, it is worth mentioning Gd(EOB-DTPA)¹⁴ (5) a very promising hepatobiliary contrast media and MS-325¹⁵ (6), which strongly interacts with albumin through noncovalent binding and appears as an efficient blood pool agent for angiography (Figure 6).

Figure 6 Structure of the hepatobiliary contrast agent Gd(EOB-DTPA) (5) and the albumin-binding agent MS-325 (6)

6.1.2 Superparamagnetic Particles

Superparamagnetic particles have been used as the active core of several preparations: large beads of polystyrene (micrometer size) coated with magnetite crystals and used as oral contrast agents, and colloidal systems made of superparamagnetic grains embedded in polysaccharide or other polymeric matrices have been applied. These particles can be targeted, according to their coating and their size, to the liver or to lymph nodes, the vascular compartment, or to antigen receptors.¹⁶ The preparation of well-characterized formulations of these materials is rather complex since not only the chemistry and the physical properties of the crystals but also their coating and final particle size have to be carefully adjusted and controlled. Although small superparamagnetic particles can be used as positive (R_1) agents (see Section 5.2) it is mainly their effect on T_2 and T_2^* which has been exploited so far (see *Contrast Agents in MRI: Superparamagnetic Iron Oxide*).

Finally it has to be stressed that the effect of these materials on the transverse relaxation of water protons critically depends on their level of aggregation and on the type of imaging procedure used. For instance, superparamagnetic particles internalized and packed in the macrophages of the liver induce a strongly multiexponential regime related to the type and timing of the echo sequence.^{17,18}

Theoretical models and computer simulations can explain these observations, which are related to the evolution of the microscopic dimensions of the system. Considering the high relaxivities and magnetic properties of these agents, the clinical doses required will be low (0.02 mmol Fe kg⁻¹ body weight).

6.2 Susceptibility Agents

As mentioned previously, susceptibility agents are aimed at inducing magnetic field gradients around the boundaries of contiguous compartments.

Dy-DTPA-BMA, a compound of the same family as the relaxation agent Gd-DTPA-BMA, has been proposed to be of use in evaluating cerebral and myocardial perfusion. Perfused zones which are made of distinct compartments will show signal decrease due to the diffusion of water through magnetic field inhomogeneities, while the signal of less or nonperfused tissues will remain unchanged due to an absence of the contrast agent or, in the case of blood-brain barrier disruption, due to its homogeneous distribution. The remaining question regarding the distinction between these last two situations can be solved by the subsequent or simultaneous administration of a relaxation agent which will modify the signal of the damaged area.

Contrary to relaxation agents which are usually injected as perfusions (unless the kinetics of uptake and clearance is studied), susceptibility agents demand higher local concentrations and thus must be administered by bolus injection and, consequently, fast imaging sequences are required. In this respect, the osmolarity of the formulation might be of concern (see Section 6.1.1).

Owing to their very high magnetization, superparamagnetic particles could also be used if their effect on T_1 is minimized by proper choice of the imaging conditions.

7 CONCLUSIONS

The first step in the development of MRI agents has led to molecular and particulate systems that influence the relaxation processes. The first generation compounds proved to be very safe and rather efficient in spite of their lack of specificity. However, it can be predicted that in the near future new compounds exhibiting better organ and disease specificity will appear.

Efforts to increase the relaxivity of MRI contrast agents require a good knowledge of the underlying physical mechanisms, and skill in various domains like coordination, colloidal, and supramolecular chemistry. Furthermore, the characterization of these agents has prompted the need for the development of dedicated instrumental and theoretical tools.

From the point of view of the doses of contrast material required by the modality, MRI is far less demanding than radiography, but more so than nuclear medicine.

Finally, some other interesting directions in contrast agent research should be mentioned, i.e. those concerning pH, pO_2 temperature-sensitive molecules, and those based on NMR signal enhancement by electron or proton magnetization transfer (see *Overhauser Effect Imaging of Free Radicals* and *Magnetization Transfer and Cross Relaxation in Tissue*).

Contrast Agents in MRI: Superparamagnetic Iron Oxide

Liliane A. Harika and Ralph Weissleder

Massachusetts General Hospital and Harvard Medical School,
Boston, MA, USA

1 HISTORY

Dextran coated iron oxide preparations were first used for in vitro magnetic resonance (MR) experiments by Ohgushi in 1978.¹ MR images of animals injected with iron oxide solutions were acquired as early as 1983. The first iron oxide enhanced MR image was published in 1985.² Within the next years, several investigators reported on the use of superparamagnetic iron oxide as an MR contrast agent.^{3,4} In 1988, results from the first clinical trials became available.⁵ Later, the use of ultrasmall iron oxides,^{6,7} monocrystalline iron oxides, and iron oxides with surface bound ligands were reported.⁸ Ligand derived iron oxides have been used for receptor imaging,^{9,10} antibody imaging and neuronal transport imaging. Currently, preclinical and clinical trials of some of these newer agents are underway.

2 SYNTHESIS

The synthesis of *non-pharmaceutical* colloidal iron oxide solutions ('ferrofluids') used for recording technology, as paint ingredients and for electromechanical devices, and the synthesis of *pharmaceutical* colloidal iron oxide solutions vary considerably. Pharmaceutical iron oxides must be water based, biocompatible, and nontoxic.

Typically, pharmaceutical grade iron oxides are synthesized by alkaline magnetite precipitation from iron(II) and iron(III) salt solutions in the presence of a carbohydrate such as dextran, dextran derivatives, or starch. The synthesis from which many iron oxides can be derived was originally described by Molday and Ohgushi.^{1,11,12} The end-products of such syntheses vary considerably, even if minor changes [temperature, pH, starting concentrations, amount of dextran/iron, iron(II)/iron(III) ratio] occur during the synthesis. Because of this variability during synthesis, pharmaceutical iron oxides are best characterized by their chemical, magnetic, and biological properties (Table 1).

Pharmaceutical superparamagnetic iron oxide preparations can be divided into four groups according to the size, blood half-life and the mechanism by which they are transported to different end organs:

- **Large Superparamagnetic Iron Oxide (SPIO).** Typically these preparations have a large variation in particle size and are usually polycrystalline. If administered intravenously, SPIO are usually characterized by a short blood half-life

Table 1 Characterization of pharmaceutical iron oxides

<i>Physical chemistry</i>
Size of the core (electron microscopy)
Chemical structure (analytical methods)
Particle size, size distribution and structure (electron microscopy, light scattering, column chromatography, sedimentation, etc.)
Crystallographic structure (X-ray diffraction)
<i>Magnetic characteristics</i>
Relaxivity in aqueous solution (relaxation time measurement)
Relaxivity in tissues (relaxation time measurement)
Bulk magnetization measurements
Relaxation behavior of spins (Mössbauer spectroscopy)
<i>Pharmacological behavior</i>
Blood half-life and biodistribution
Organ, tissue, target capture coefficients
Degradation and elimination
Toxicity

(<15 min) and a predominant uptake by phagocytic cells of the reticuloendothelial system in liver and spleen. SPIO have also been used as the active ingredient for MR contrast agent of the gastrointestinal tract.

- **Ultrasmall Iron Oxide Preparations (USPIO) and Monocrystalline Iron Oxide (MION) Preparations.** These are chemically similar to agents described above, but have a smaller size (usually <30 nm as determined by laser light scattering). Because of their smaller size and often higher dextran/iron ratio, agents of this class are capable of slowly leaving the vascular system, and are commonly taken up by macrophages of lymph nodes, spleen, and bone marrow.
- **Receptor-Directed Iron Oxides.** These consist of iron cores to which are bound carbohydrates with receptor specificity (e.g. arabinogalactan), or of dextran iron oxides the surfaces of which have been modified with receptor-specific ligands. Preparations with affinity to asialoglycoprotein (ASG) receptors on hepatocytes and to cholecystokinin receptors on pancreatic cells, have been reported.
- **Antibody-Labeled Iron Oxides.** These usually consist of small iron oxides (e.g. MION) derivatives, to which have been covalently bound antibodies or antibody fragments.⁸

3 MAGNETIC PROPERTIES

The magnetic properties of iron oxide solutions are governed by the chemical structure, packing of the iron oxide core (Table 2) and the presence or absence of aggregation of individual crystals into larger clusters, in solution or inside cells. Pharmaceutical iron oxides usually exhibit superparamagnetic behavior (no remnant magnetization at zero field strength; induced magnetization is not linear with increasing magnetic field).

Iron oxides decrease proton relaxation times (T_2^* , T_2 , T_1) of tissues in which they accumulate or to which they are distributed. The effect on T_2^* relaxation times usually predominate; however, effects on tissue T_1 relaxation times become more prominent as the diameter of the iron oxide cores become

Table 2 Characteristics of different iron oxide compounds

Parameter	Magnetite	Maghematite	Hematite	Oxyhydroxide
Formula	Fe_3O_4	$\gamma\text{-Fe}_2\text{O}_3$	$\alpha\text{-Fe}_2\text{O}_3$	FeOOH
Magnetic strength ^a	4	4	0–0.01	1–2
Crystallography	Inverse spinel	Inverse spinel	HCP ^b	CCP ^c

^aBohr magneton/unit formula. ^bHCP, hexagonal closed packed. ^cCCP, cubic closed packed.

smaller.¹³ Because of these effects, MR imaging in patients who have received iron oxides is usually done with T_2 -type pulse sequences, proton density sequences, and gradient echo pulse sequences.

4 CLINICAL APPLICATIONS

4.1 Liver Imaging

A variety of agents have been or are currently being tested for liver imaging by the following pharmaceutical companies: Advanced Magnetix, Schering, Nycomed, Bristol-Myer-Squibb, Mallinkrodt, and Guerbet. After intravenous administration of most agents (usual intravenous dose 10–20 μmol Fe per kg), liver signal intensity decreases, whereas that of liver metastases remains unchanged or is only minimally changed. Because of this differential enhancement pattern, hepatic tumors become more conspicuous. Usually, liver signal intensity returns to precontrast values within several days as iron oxide particles are degraded within phagolysosomes of macrophages (Figure 1).¹⁴ As a general rule, mildly T_2 -sensitive spin echo or T_2^* -dependent gradient echo sequences show the greatest decrease in liver signal intensity.

Early clinical reports on the efficacy of iron oxides are equivocal. Whereas some authors have found an increase in lesion conspicuity and an improved contrast-to-noise (C/R) ratio with the use of iron oxides, other authors have concluded that these agents do not substantially improve diagnosis in a clinical setting. The latter have claimed that the decrease in liver signal-to-noise (S/N) ratio makes visualization of normal anatomic structures difficult. Another often cited disadvantage of iron oxide enhanced MR imaging, is the low S/N ratio of pulse sequences required to exploit the T_2^* and/or T_2 effect of iron oxides.

Other studies have evaluated the use of iron oxide in cirrhosis, hepatitis, and acute hepatic failure.¹⁵ These studies have shown that the uptake is inhomogeneously altered in cirrhosis, and homogeneously decreased in hepatitis. On the basis of these and other experimental studies, it has been concluded that superparamagnetic iron oxides can be used as an imaging marker of reticuloendothelial function.¹⁵

4.2 Spleen

The rationale for using iron oxides for imaging of the spleen is similar to that of liver imaging. Iron oxide particles are phagocytosed by splenic macrophages, but not (or to a much lesser degree) by splenic metastases. Metastases thus become

more conspicuous because of their relative lack of such macrophages.

Clinical trials have confirmed that splenic mass lesions can be more reliably detected with iron oxide enhanced MRI than by other conventional imaging methods (contrast enhanced computed tomography).¹⁶ Iron oxide has also been used for the differentiation of normal spleens and spleens diffusely infiltrated by lymphoma.¹⁷ Phagocytosis of superparamagnetic iron oxide in lymphomatous spleens is reduced because of diffuse displacement of splenic macrophages by lymphomatous cells and/or by immunologic suppression of macrophage activity. Since phagocytosis is not significantly reduced in reactive splenomegaly, splenic signal intensity decreases after administration of iron oxide to a similar extent as in normal spleens, enabling the differentiation of some causes of splenomegaly, on the basis of signal intensity.

4.3 Lymph Nodes

Experimentally, several contrast agents have been used for MR lymphography, and different administration routes have been studied: subcutaneous,¹⁸ intralymphatic,¹⁹ intravenous, and intraarterial. Of these techniques, the intravenous mode appears to be the preferred one, because it is capable of delivering the contrast agent to all 600–800 human lymph nodes following a single administration.

In order for iron oxides to accumulate in lymph nodes, certain prerequisites must be met. Firstly, iron oxides must have a small hydrodynamic radius size, in order to gain access to the interstitium via capillary pores.²⁰ Secondly, lymphotropic iron oxides must have a long blood half-life in order to minimize rapid extraction by liver and spleen. Ultimately, iron oxides have to express surface characteristics that enable them to be recognized by phagocytic cells within lymph nodes.

At the time of writing, only one clinical study has evaluated the use of an ultrasmall iron oxide preparation for imaging of cervical lymph nodes in human volunteers. The dose employed was higher (>1.7 mg Fe per kg) than that for liver–spleen imaging because of lower nodal accumulation efficiency.²¹ To determine whether iron oxide based lymphotropic agents will ultimately be clinically useful for cancer staging, controlled clinical trials are required.

4.4 Gastrointestinal Tract

Different iron oxide preparations (OMP, AMI-121), have been used as ‘negative’ (i.e. darkening of luminal contents) gastrointestinal contrast agents.^{22,23} Enhanced images usually show improved delineation of the head of the pancreas, para-aortic regions and anterior margins of the kidneys. There is currently no consensus in the radiologic community whether

Figure 1 Detection of hepatic and splenic metastases using a superparamagnetic iron oxide preparation. (a) Nonenhanced spin echo (SE) 1500/42 MR image. Multiple hepatic metastases appear slightly hyperintense. The splenic tumor is undetectable. (b) SE 1500/42 MR image obtained 1 h after intravenous administration of a superparamagnetic iron oxide (AMI-25; $30 \mu\text{mol kg}^{-1}$). Multiple hepatic metastases are now easily detected in both liver lobes, and one-half of the spleen is replaced by a solid tumor. This image demonstrates the efficacy of superparamagnetic iron oxides for enhancing tumor–liver/spleen contrast. (c) Three days after administration, the contrast between tumor and surrounding liver and spleen has decreased because of biodegradation of the iron oxide particles. (Reprinted with permission from *Radiology*)

the routine use of such agents will ultimately improve the detection of intraabdominal pathology.²² Because of the high osmotic load, a significant amount of patients experience diarrhoea, nausea, and vomiting.

5 EXPERIMENTAL USE

5.1 Bone Marrow

Different iron oxides have been used as contrast agents for bone marrow imaging.⁷ In vivo MR imaging of rabbits and rats has confirmed that certain small iron oxides decrease the signal intensity of red and yellow marrow. The decrease in signal intensity is usually most marked with gradient echo pulse sequences. Iron oxides can potentially be used to differentiate between normal and abnormal red marrow and between tumor deposits and hyperplastic red marrow, as shown in animal studies.

5.2 Blood Pool Imaging

It has been shown that a single intravenous administration of small iron oxide preparations (e.g. MION) has a significant R_1 effect and that this effect can be exploited to decrease the T_1 of blood over prolonged periods of time (blood half-life in rodents 3 h). Animal experiments have shown that 15–50 $\mu\text{mol Fe per kg}$ (0.8–2.8 mg Fe per kg) of MION resulted in a three- to four-fold increase in aortic S/N ratio, and in an improvement in the image quality of pulmonary, abdominal, and extremity vasculature by MR angiography.²⁴

Iron oxide preparations have also been used experimentally to assess myocardial perfusion (conventional iron oxides).^{8,25} For example, myocardium supplied by an occluded coronary artery does not decrease in signal intensity following injection of the iron oxide, whereas normally perfused myocardium decreases homogeneously in signal intensity.

5.3 Receptor Agents

Certain galactose-containing iron oxide preparations can be delivered to ASG receptors on hepatocytes. MR imaging with such receptor agents, has demonstrated that a significant decrease in liver S/N ratio can be obtained at lower doses of iron oxide than with conventional iron oxides. This is presumably due to the effective cell adhesion, internalization, high receptor density or different spatial distribution, as compared to reticuloendothelial-system-specific iron oxides.

The main impetus for developing receptor specific liver agents is to enable functional MR imaging. For example, primary malignant hepatic tumors lose the expression of the ASG cell surface receptor during malignant degeneration, and, therefore, are not expected to take up ASG-receptor agent. Furthermore, ASG-receptor agents potentially allow differentiation of ASG(–) (i.e. malignant tumors such as hepatocellular carcinoma and ASG(+)) (i.e. benign tumors such as focal nodular hyperplasia (FNH) or adenoma). Direct targeting of hepatocytes, rather than hepatic phagocytic cells, also allows direct assessment of hepatic function as shown in animal models of diffuse liver disease.

Figure 2 Detection of myocardial infarction with MION-antimyosin. MR microscopic T_2 -weighted images of an infarcted rat heart with: (a) no contrast, (b) MION (control), or (c) MION-antimyosin. Only in (c) is there a significant decrease in signal intensity of damaged myocardium (arrow). (Reprinted with permission from *Radiology*)

5.4 Antibody Imaging

To assess myocardial viability by MR imaging, MION has been coupled to an antimyosin.⁸ One hour after intravenous administration of MION-antimyosin to rats or rabbits, a marked decrease in the signal intensity of infarcted myocardium was observed, whereas the signal intensity of normal myocardium was essentially unaltered (Figure 2). This and other agents, may have future applications for in vivo tissue typing, tumor diagnosis, and differential diagnosis.

5.5 Other Uses

A variety of different experimental iron oxide preparations have been used for MR experiments. 'Ferrosomes', lipid vesicles loaded with superparamagnetic iron oxide crystal aggregates, have been used for MR imaging. Attachment of tumor-specific monoclonal antibodies to iron oxide aggregates has been described, as well as introduction of the iron oxide particles into the fetal neural tissue. Axonal transport has also been studied using wheat germ agglutinin labeled iron oxide.

1 INTRODUCTION

During the first decade since its introduction into clinical medicine, magnetic resonance (MR) has developed into a highly sensitive imaging modality with great flexibility. While many intrinsic and extrinsic parameters can alter MR image appearance, differences in tissue proton relaxation times, (T_1 and T_2) provide the dominant source of image contrast between normal and disease states. Because of this excellent tissue contrast, it was originally felt that MR, unlike other techniques, would not require the administration of exogenous contrast agents. However, it soon became apparent that relaxation times of normal and abnormal tissue, such as meningiomas and small metastases, can overlap with normal tissue, resulting in decreased diagnostic sensitivity and specificity.¹ The introduction of paramagnetic contrast agents has overcome many of these problems. In addition, 'magnetopharmaceuticals' can also be used to assess physiologic processes (e.g. tissue perfusion), and newer agents have the potential for target specific (receptor and antibody) imaging. Thus, MR contrast agent imaging combines the advantages of high spatial resolution with the functionality of nuclear medicine imaging. This offers both a challenge and an opportunity to the radiology community. This article provides an overview of the principles of MR contrast agents and reviews new agents for enhancement of the liver, lymph nodes, and vessels.

2 PRINCIPLES

A paramagnetic substance is one that contains one or more unpaired electrons which enhance the relaxation rates ($1/T_1$ and $1/T_2$), i.e. shorten T_1 and T_2 relaxation times, of water protons. The pharmaceutical manipulation of tissue signal intensity arises from the interaction of the magnetic moments of protons with the magnetic moments of these materials. Unlike iodinated radiographic and radionuclide agents, paramagnetic agents have an indirect effect on image intensity. The alteration in the observed MR image intensity is the result of decrease in the proton relaxation times: the agent per se is not 'imaged'. In addition, the effect on MR signal intensity is not straightforward but depends on several factors including:²

- Magnetic moment.
- Concentration.
- Dipole-dipole distance ($1/r^6$).
- Magnetic field strength.
- Water exchange.
- Rotational motion.

It is the magnitude of the magnetic moment that is principally responsible for enhanced proton relaxation and alteration of image signal intensity. Gadolinium (Gd), a lanthanide series element, is the most potent paramagnetic element, possessing seven unpaired electrons. Thus, Gd has received considerable attention, although other paramagnetic metal ions such as manganese and iron, both of which possess five unpaired electrons, are currently being investigated. In the design of a clinically useful magnetopharmaceutical one must not only consider the relaxation efficiency but also pay close attention to potential in vivo toxicity. While metal ions are very efficient relaxation agents, they are quite toxic. Chelation of the ion with a suitable organic ligand [e.g. diamine tetracarboxic pentaacetic (DTPA)] dramatically reduces toxicity, but also leads to diminished relaxivity since the ligand prevents close interaction between water protons and the paramagnetic ion. The attachment of various carrier molecules will also affect the tissue distribution and determine the clinical use of the agent.

2.1 T_1 Agents

In practice, the radiologist has little control over many of these factors. In general, it is the biodistribution and resulting tissue concentration of an MR contrast agent that determines the change in MR signal intensity. T_1 shortening enhances tissue signal, while T_2 shortening decreases tissue signal intensity. Although paramagnetic species equally enhance both T_1 and T_2 relaxation rates, at clinically recommended doses, T_1 effects dominate the alteration in image signal intensity. Therefore, paramagnetic metal substances are known as ' T_1 agents'.

2.2 T_2 Agents

Superparamagnetic iron oxide particles (IOPs) are a new class of MR contrast agents that predominantly effect T_2 relaxation. These particles, which have very large magnetic moments (2–3 orders of magnitude greater than those of paramagnetic metal ions) and associated magnetic field gradients, are referred to as 'homogeneity spoilers'.³ When water molecules diffuse through these induced field gradients, protons experience spin dephasing (T_2^* relaxation) which leads to decrease in MR signal intensity. The initial IOP preparations with a relatively large size (>50 nm) are rapidly taken up by reticuloendothelial cells of the liver and spleen and produce 'negative' contrast. New ultrasmall iron oxide particles (USIOPs) with a size of <10 nm pass through capillaries and reach the macrophages in lymph nodes. These preparations are discussed in *Contrast Agents in MRI: Superparamagnetic Iron Oxide*.

3 CLINICALLY APPROVED AGENTS

In 1988, gadolinium DTPA (Gd-DTPA, Magnevist[®], Schering AG, Berlin) became the first MR contrast agent to be

approved for clinical use. Administered intravenously, Gd-DTPA has an extracellular distribution (analogous to the iodinated radiographic agents) and undergoes rapid renal excretion by glomerular filtration.⁴ In humans Gd-DTPA has a plasma half-life of <15 min and >90% can be recovered in the urine within 3 h following intravenous administration. Enhancement of the MR image signal is obtained at doses of 0.1–0.2 mmol kg⁻¹ with a median lethal dose (LD₅₀) of approximately 10 mmol kg⁻¹. This results in a safety factor of approximately 50–100, which is superior to that of iodinated compounds.

Recently, three additional gadolinium chelates have been approved for clinical use: Gd-DTPA-bis(methyl)anoide (Gd-DTPA-BMA, Omniscan[®], Nycomed), Gd-HP-DO3A (Gadoteridol, ProHance[®], Squibb Diagnostics), and Gd-DOTA (DOTAREM[®] Guerbet). All three agents possess an electrically neutral charge and lower osmolality, potentially offering greater safety for high-dose studies and rapid bolus injections. A more complete description of gadolinium chelates can be found in *Gadolinium Chelates: Chemistry, Safety, and Behavior*.

3.1 Clinical Applications of Gadolinium Chelates

Gadolinium chelates are frequently used in central nervous system (CNS) imaging, while their role in body MR imaging is still evolving. In addition to dosage, appropriate selection of MR pulse sequences and acquisition time following injection are critical for certain applications. Due to their extracellular distribution, gadolinium chelates highlight breakdown of the blood–brain barrier and detect small lesions missed on conventional T_1 -weighted imaging (Figure 1). In the brain and spine, gadolinium chelates have a high sensitivity in detecting pathologic conditions⁵ including:

- Primary and secondary malignancies.
- Infectious processes.
- Activity of multiple sclerosis plaques.
- Extraaxial lesions, especially small neuromas and meningiomas.
- Differentiating scar from recurrent disk.

The role of these interstitial agents in CNS disease, as well as their application in the cardiovascular and musculoskeletal

systems, is addressed in greater detail in other articles in this volume.

4 NONAPPROVED AGENTS

While interstitial T_1 agents have demonstrated clinical utility, these agents have been less successful in identifying pathology in the liver and lymph nodes and for enhancement of vessels in MR angiography. Thus a significant effort has been made to develop MR agents that are tissue specific.

4.1 Oral Contrast Agents

A major limitation of MR imaging in the abdomen has been the lack of a bowel contrast agent. These are required in order to differentiate bowel loops from normal and pathological anatomy. In general, oral contrast media may be categorized as positive-enhancing T_1 agents or negative-enhancing T_2 agents.⁶ Positive enhancers include Gd-DTPA and ferric ammonium citrate. Gd-DTPA dimeglumine dissolved in mannitol (Magnevist enteral[®], Schering) has been developed as an oral agent with positive bowel lumen enhancement. In a multicenter clinical trial, gastrointestinal enhancement improved the definition of abdominal mass lesions in 62% of cases. Ferric ammonium citrate, known as a supplemental source of iron in geritol (Beecham, Bristol) has been shown to improve the delineation of gastric margins, pancreas, and colon in normal volunteers.

Different iron oxide preparations have been used as negative gastrointestinal negative contrast agents.⁷ Images obtained before and after ingestion of the contrast material at doses of 22.5–225 mg Fe in a volume of 600–900 mL demonstrated delivery of contrast material into the distal small bowel. The enhanced images showed improved delineation of the head of the pancreas, para-aortic regions, and anterior margins of the kidneys. The contrast agent did not generate MR artifacts.

4.1.1 MR Agents in Liver Imaging

The detection and differentiation of hepatic tumors have important diagnostic and therapeutic implications in cancer patients.⁸ However, conventional MR imaging of the liver is limited by motion artifacts and intrinsic contrast between lesions and normal liver tissue. The combination of nonspecific interstitial agents with conventional MR imaging can result in lower lesion to liver contrast.⁶ Because of the transient effects with these agents, fast MR imaging is required to detect lesions. However, there are several approaches to enhancing liver tissue that can be used with conventional MR imaging, including targeting of agents to hepatocytes. (Use of IOPs for targeting the reticuloendothelial system is discussed in great detail in *Contrast Agents in MRI: Superparamagnetic Iron Oxide*).

4.2 Hepatobiliary Agents

The design of MR contrast agents for the hepatobiliary system is based on the chelation of paramagnetic ions to ligands with high affinity for hepatocytes. Subsequent to the initial demonstration in animals that Fe-EHPG is taken up by hepatocytes and excreted into the bile,⁹ three new hepatobiliary agents

Figure 1 T_1 -weighted MR brain images in a patient with metastatic cancer before (a) and after (b) Gd-DTPA. While an abnormality with mass effect is visible in (a), Gd-DTPA provides enhancement of the metastatic focus [long arrow in (b)], and a second, unsuspected lesion [small arrow in (b)] is detected on the opposite side

have been developed including manganese(II) *N,N'*-dipyridoxal-ethylenediamine-*N,N'*-diacetate-5,5'-bis(phosphate) (Mn-DPDP; Salutar, Nycomed), Gd-BOPTA (Bracco) and Gd-EOB(ethoxybenzyl)-DTPA (Schering). Initial clinical findings show encouraging results.

4.2.1 Mn-DPDP

Mn-DPDP is a manganese chelate of pyridoxal-5'-phosphate, a catalytically active form of vitamin B₆, and is therefore recognized by the cell-membrane transport system.¹⁰ Since uptake of Mn-DPDP is thought to be related to liver cell function only those parts of liver tissue with preserved hepatocellular function show enhancement after injection of Mn-DPDP.¹¹ Because of relatively slow excretion of the agent, liver enhancement is visible 10–23 h postinjection. This extended 'imaging window' provides adequate time for patient preparation and multiple MR imaging techniques.

In Phase I and II trials, patients with liver metastases demonstrated significant increase in tumor–liver contrast-to-noise (C/N) ratio after the injection of 10 and 5 $\mu\text{mol kg}^{-1}$ Mn-DPDP on T_1 -weighted images (Figure 2). The highest increase in C/N ratio was achieved with the fast and heavily T_1 -weighted gradient recalled echo (GRE) imaging techniques.¹² The confidence level of lesions detected increased after the injection of Mn-DPDP and the number of small lesions (≤ 1.0 cm diameter) detected was considerably higher as compared with unenhanced MR images.

In patients with primary hepatocellular carcinoma (HCC), uptake of Mn-DPDP was found to vary. In patients with well differentiated HCC, marginal or inhomogeneous uptake of the contrast agent was noticed; however, in patients with dedifferentiated HCC no uptake of Mn-DPDP was found. In these patients nodules obscured on unenhanced T_1 - and T_2 -weighted images due to peritumoral edema were clearly visible after administration of Mn-DPDP. Tumor enhancement in HCC has also been investigated experimentally, demonstrating that tumoral uptake depends on tumor differentiation with peripheral rim enhancement in highly malignant tumors and late central enhancement in differentiated tumors.¹³ These findings were confirmed more recently in the US Phase II trial when primary tumors of the liver like fibronodular hyperplasia (FNH), adenoma, regenerative nodule, HCC, and fatty infiltration also demonstrated enhancement.¹⁴

Extrahepatic enhancement after the injection of Mn-DPDP was found to varying degrees in pancreatic tissue, cortical zones of the kidneys, and stomach wall. This is most likely due to instability of the complex resulting in dissociation to some degree with uptake of free manganese in the tissues listed. Pancreatic enhancement has been exploited for contrast-enhanced MRI of the pancreas, improving visualization of pancreatic disease. Despite the concerns of free manganese, preclinical animal studies have shown that the safety factor (ratio of the acute toxicity to dose used for imaging) of Mn-DPDP is similar to that of Gd-DTPA.¹⁵ None of the patients studied showed signs of severe allergic reactions, but minor side-effects were found in 28/141 patients (19.5%). Neither significant electrocardiogram (ECG) changes nor significant changes in vital signs were seen after the injection of Mn-DPDP.

Figure 2 (a) T_1 -weighted SE 500/15 image shows metastases hypointense relative to uninvolved liver. (b) T_1 -weighted SE 500/15 image after administration of 10 $\mu\text{mol kg}^{-1}$ Mn-DPDP shows metastases hypointense relative to enhanced, uninvolved liver tissue. Note the improved lesion–liver contrast and detectability of small hepatic metastases as compared with unenhanced MR images

4.2.2 Gd-BOPTA/Dimeg

Gd-BOPTA (Gadobenate Dimeglumine) is a hepatobiliary agent that is similar to Gd-DTPA, differing only in the substitution of a CH_3 group by a benzyloxymethyl side chain. The molecule is recognized by the transmembrane carrier protein within the hepatocyte cell membrane, and thus represents a liver specific drug.¹⁶ Intravenous administration of Gd-BOPTA shortens T_1 values of liver parenchyma for a prolonged period of time, thus increasing liver signal intensity on T_1 -weighted images. Since most malignant liver tumors are devoid of the transmembrane carrier protein, tumor–liver contrast increases for more than 2 h.¹⁷ Contrast is especially high on late images (>45 min postinjection).

Phase I studies demonstrated enhancement almost independent of biliary elimination kinetics. Peak liver enhancement

occurred 40–45 min following intravenous administration of 0.1 mmol kg^{-1} body weight, with a slow decrease over several hours. The European Phase II trial of Gd-BOPTA has demonstrated convincing tolerance and safety data, with mild or moderate side effects in less than 2% of 359 patients. Figure 3 demonstrates the clinical utility of Gd-BOPTA.¹⁸ Nonspecific enhancement in tumor tissue during or immediately after administration of Gd-BOPTA was also observed during the Phase II trial. An additional application is the detection and characterization of myocardial ischemia.¹⁸

4.2.3 Gd-EOB-DTPA

Gd-EOB-DTPA is a derivative of Magnevist[®], modified by substitution of a side chain altering pharmacokinetics and bio-distribution in vivo.¹⁹ The agent is a hepatocyte-directed contrast agent that is preferentially cleared by the hepatocellular organic anion system and subsequently excreted into bile. Previous studies in rats have shown that 63–80% of Gd-EOB-DTPA is excreted in bile;²⁰ 20–37% of the injected dose is eliminated through the kidneys by means of glomerular filtration. The plasma half-life of Gd-EOB-DTPA in rats is approximately 10 min.¹⁹

Gd-EOB-DTPA has a T_1 relaxivity of 16.6 L mmol^{-1} in liver tissue of rats. With a median lethal dose of 10 mmol kg^{-1} in mice and rats after intravenous injection, Gd-EOB-DTPA seems to have a fairly high margin of safety. The safety factor in rats of 400 is higher than any other factor for a clinically approved contrast agent in radiology.²¹ Up to 75% of this

agent is excreted by the hepatobiliary system, and more than 200% liver enhancement is achieved at a dose of 0.1 mmol kg^{-1} . As demonstrated recently, this agent may also be used to perform MR cholangiography.

Tumor–liver contrast is improved since malignant lesions demonstrate only nonspecific enhancement via the extracellular space.²² Contrast is achieved 3–5 min following the administration of $30 \mu\text{mol kg}^{-1}$, and remains high for more than 30–60 min.²³ Potential clinical applications besides liver imaging are imaging of the biliary tract and the upper small bowel.

4.3 Vascular Agents

A number of different angiographic MR techniques have been described for various applications. Previous reports have clearly demonstrated that vessel-to-background ratios, and thus image quality, can be significantly improved by decreasing blood T_1 with paramagnetic contrast agents and optimizing pulse sequences. Whereas Gd-DTPA decreases blood T_1 in cerebral vessels without significantly increasing the signal intensity of the CNS, short blood half-life and rapid extravasation into the extravascular space limits the usefulness of low molecular weight paramagnetic MR contrast agents in the remainder of the body. Despite some interesting results with slow infusion of Gd-DTPA, several macromolecular agents with a longer intravascular distribution have been developed.

Ideal macromolecular MR angiographic contrast agents should have a distribution limited to the intravascular space, a sufficiently long blood half-life, and no immunogenicity. In addition, the agent together with chelated metal ion should be excreted in toto. To achieve this, chelating groups have been attached to a variety of natural or synthetic macromolecules [e.g. proteins, polysaccharides, poly(L-lysine), polyethylene-imine].²⁴ Chemical attachment (conjugation) of DTPA to bovine serum albumin (BSA) results in a macromolecular label with a longer blood half-life than that of Gd-DTPA. Unfortunately, large doses of labeled BSA have to be administered to achieve sufficiently high concentrations of the paramagnetic label in blood. In addition, BSA-Gd-DTPA has been found to be immunogenic and thus potentially anaphylactic.²⁵ Synthetic polypeptides, such as poly(L-lysine), offer an alternative to natural macromolecular carriers. Poly(L-lysine) modified with DTPA has been shown to be an effective carrier molecule for paramagnetic or radioactive cations.²⁶ The toxicity and immunogenicity profile of poly(L-lysine)-Gd-DTPA is better than that of albumin-Gd-DTPA. Despite these significant advantages over protein-based macromolecular agents, poly(L-lysine)-Gd-DTPA (molecular weight 48.7 kDa) is rapidly removed from blood.²⁷ Larger poly(L-lysine) molecules have been reported to exhibit a longer residence in the blood pool.

Bogdanov et al.²⁸ reported a new macromolecular agent consisting of monomethoxy ether of poly(ethylene glycol) 5000 (MPEG5) covalently attached to a poly(amino acid), wherein the poly(amino acid) serves as the carrier of Gd-DTPA. Experiments in animals have demonstrated two major features: (1) absence of immune response against Gd-DTPA and the carrier molecule following intravenous administration; and (2) minimal accumulation of the agent in the reticuloendothelial system. Bio-kinetic studies revealed that the blood half-life of the agent is 14 h. The new agent [MPEG-poly(L-lysine)-Gd-DTPA], has a high R_1/Gd relaxivity of 18.0 (mM s)^{-1} compared with Gd-DTPA

Figure 3 Axial T_1 -weighted images at 1.5 T in a patient with colon carcinoma before (a) and 120 min following (b) intravenous administration of 0.1 mmol kg^{-1} body weight Gd-BOPTA (Dimeg). Tumor–liver contrast is increased on the postcontrast image, improving detection of metastases, i.e. more lesions are visualized. (Reproduced by permission of F. Cavangna, Ph.D., Bracco AG, Italy)

Figure 4 Tumor neovasculature in a rat with R3230 adenocarcinoma implanted in a left flank. (a) MR angiography (3D-TOF, $TE = 8$ ms, $TR = 60$ ms, 60°); (b) polymer cast. The MR imaging results and the polymer replica of the vasculature were obtained from the same animal. Note iliac and epigastric venous in-growth in the tumor

$[3.7 \text{ (mM s)}^{-1}]$ and poly(L-lysine)-Gd-DTPA $[13.1 \text{ (mM s)}^{-1}]$. Dose-response studies demonstrate that doses of $20 \mu\text{mol Gd kg}^{-1}$ are sufficient to increase the vessel/muscle ratio four- to five-fold using three-dimensional 'time-of-flight' (3D-TOF) MR angiographic pulse sequences. Contrast is significantly improved and remains unchanged for at least 2 h after intravenous administration allowing good visualization of small and peripheral vessels (Figure 4).

4.4 Lymph Node Agents

Detection of lymph node metastases is a critical part of cancer staging.²⁹ Conventional MR imaging offers the advantages

of high spatial resolution and inherent soft tissue contrast to distinguish nodes from adjacent fat, muscle, and vessels.³⁰ Unfortunately, because in vitro measurements of human T_1 and T_2 relaxation times of normal, metastatic, lymphomatous, and hyperplastic lymph nodes demonstrate considerable overlap, these parameters by themselves are of limited clinical utility.³¹ Thus, MR detection of lymph node metastases (i.e. size criteria) has the same limitations as X-ray computed tomography.

A method of MR lymphography which delivers contrast agent to all 600–800 human lymph nodes with a single intravenous administration would be an ideal clinical tool. Currently, research efforts are concentrated in maximizing the delivery of iron oxide (see *Contrast Agents in MRI: Superparamagnetic Iron Oxide*) and specific T_1 agents to lymph nodes. Initial attempts to perform MR imaging with Gd-DTPA labeled target-specific carrier molecules has failed because of the necessity to deliver large amounts of paramagnetic labels to the target tissue (10^{-4} M), considerably higher amounts than necessary for scintigraphy (10^{-11} M). Recently, Papisov et al.³² reported a targeted T_1 -label, polyglucosylated macrocomplex (PGM), which accumulates in lymph nodes to a high degree after intravenous administration. This agent consists of a poly(L-lysine) backbone to which Gd-DTPA molecules are attached. To prevent uptake by the reticuloendothelial system cells, a peripheral dextran coating is also attached which sterically protects the inner T_1 macromolecular labels [e.g. Gd-DTPA-poly(L-lysine)] from recognition. Intravenous administration of 10 mg kg^{-1} of a double labeled (^{111}In , Gd) preparation in rats resulted in significant uptake at 24 h in central lymph nodes ($35\text{--}45\%$ dose g^{-1}), spleen ($15\text{--}30\%$ dose g^{-1}), while only 1–2% accumulated in liver. The uptake in lymph nodes reflected their activity, with significantly increased accumulation in the lymph nodes draining sites of inflammation (100% dose g^{-1} or more). Fat saturated T_1 -weighted MR images clearly demonstrate lymph node enhancement (Figure 5). As other molecules can be incorporated into the PGM complex, e.g. chemotherapeutic agents, this class of agent may also play a role in drug delivery to lymph nodes.

Figure 5 Fat suppressed T_1 -weighted MR images ($700 \mu\text{m}$ slices) of the popliteal fossa in a rat, demonstrating enhancement of lymph nodes, 3 h after intravenous injection of $10 \mu\text{g kg}^{-1}$ of PGM

5 SUMMARY

MR contrast agents, both paramagnetic and superparamagnetic susceptibility agents, enhance proton relaxation rates and provide improved lesion detection with MR imaging. Interstitially distributed gadolinium chelates have a demonstrated utility in CNS disease. However, it is likely that tissue specific agents will be required for MR imaging of the liver, vessels, or lymph nodes. Agents are now available at various stages of development in these three areas. Further developments in MR contrast media, in combination with improved imaging techniques may lead to expansion and novel applications of diagnostic MR imaging.

Biographical Sketches

Thomas J. Brady. b 1946. B.S., King's College, 1968; M.D., Loyola, 1972. Currently Director, MGH-NMR Center, Department of Radiology, Massachusetts General Hospital and Harvard Medical School, Charlestown, MA, USA. Approx. 160 publications. Research interests include evaluation of novel MR contrast agents.

Peter Reimer. b 1959. M.D., FRG, 1985. Currently Head of MR at the Institute of Clinical Radiology, Westfälische-Wilhelms University, Munster. Major research interests include clinical application of cell specific MR contrast agents and ultrafast MR imaging techniques.

Gadolinium Chelate Contrast Agents in MRI: Clinical Applications

Val M. Runge

University of Kentucky, Lexington, KY, USA

1 INTRODUCTION

Intravenous contrast administration, utilizing water soluble gadolinium chelates, has assumed an increasingly important role in clinical magnetic resonance imaging (MRI)¹ during the last 5 years. The positive impact of this new class of contrast media on overall health care is clear from the high level of use.^{2,3} For example, in the USA more than half of all head examinations and more than a quarter of all spine examinations are currently performed with intravenous contrast injection. Current utilization is less in anatomical regions outside the head and spine, although definite indications exist in body MRI. Worldwide, four chelates are in use in humans—gadopentetate dimeglumine [NMG₂(Gd DTPA)], gadoterate meglumine [NMG(Gd DOTA)], gadodiamide (Gd DTPA-BMA), and gadoteridol (Gd HP-DO3A). (NMG⁺ is the *N*-methylglucammonium ion.) The relaxivities, and thus the contrast effects, are comparable for these agents when given at standard dose (0.1 mmol kg⁻¹). Increased efficacy has been demonstrated at high dose (0.3 mmol kg⁻¹) in certain disease states, in particular for the detection of intracranial metastatic disease. In these applications, the more stable ring chelates, gadoterate meglumine and gadoteridol, offer a higher theoretical safety margin. (Further information on the structure of these chelates is given in *Gadolinium Chelates: Chemistry, Safety, and Behavior*.)

In head imaging, contrast administration provides improved lesion recognition and characterization. Disease states for which contrast enhancement is indicated include neoplasia, infarction, infection, and other inflammatory conditions. In spine imaging, contrast administration primarily improves diagnostic specificity, although in certain instances improved lesion detectability is also provided. Foremost in spine applications is the use of contrast to differentiate scar from disk material in the postoperative patient, with the identification of recurrent or residual disk herniation an indication for surgery in the appropriate clinical setting. In body imaging, the primary indication at present for contrast use is in the liver for improved lesion characterization. Early postcontrast scans can also be used to improve liver lesion detection. Elsewhere in the body, applications exist principally with regard to improved lesion characterization.

2 CLINICAL APPLICATIONS IN THE HEAD

Diseases of the head and its contents can be subdivided by type into four categories: neoplasia, infarction/vascular dis-

orders, infection/inflammatory disease, and congenital lesions. Clinical referrals for MRI come principally from the first three categories. Contrast administration provides such critical information in these patients as to be mandated.⁴ The fourth category, congenital disease, is smaller, and for purely structural lesions in this group use of contrast is not indicated. However, in many instances these patients also manifest related neoplastic, vascular, or inflammatory conditions for which contrast administration is indicated. Several prospective clinical trials have been conducted examining the question of efficacy for contrast administration in all patients referred for head MRI. In one such study, contrast administration was judged to change scan interpretation significantly in 25% of cases, with both the failure to identify lesions (5%) and misdiagnosis (20%) contributing to the lower efficacy of precontrast scans.⁵ In addition to demonstrating the value of abnormal contrast enhancement, these trials revealed that the absence of abnormal contrast enhancement can provide important diagnostic information.⁶

With intra-axial primary brain tumors, contrast enhancement principally provides information with regard to lesion characterization (Figure 1). Low-grade astrocytomas in general do not enhance, while higher grade lesions (anaplastic astrocytomas and glioblastomas) demonstrate substantial disruption of the normal blood-brain barrier and thus abnormal contrast enhancement. In the differentiation of these tumors, the identification of an irregular thick rim of enhancement with central necrosis points to the diagnosis of a glioblastoma multiforme. It is important, however, to note that in glial cell tumors abnormal contrast enhancement does not correlate precisely with lesion extent. The presence of tumor cells beyond the area of blood-brain barrier disruption noted on scans has been demonstrated in histologic studies. Contrast enhancement in glial cell tumors can also be used to direct surgical biopsy, as enhancing portions of a lesion tend to be of higher grade. Enhancement is also important for clinical follow-up, with recurrence or progression most easily recognized in higher grade lesions on the basis of abnormal contrast enhancement.

With intra-axial metastatic disease, contrast administration is crucial for lesion identification. Many small metastatic lesions are isointense to surrounding brain on precontrast scans, mandating contrast administration for recognition (Figure 2). Enhanced MRI is now recognized as the modality of choice for detection of intracranial metastases, with markedly improved sensitivity relative to X-ray computerized tomography (CT). In one study of 23 patients suspected of having cerebral metastases, enhanced MRI revealed 67 lesions, as compared with 40 lesions on precontrast *T*₂-weighted MRI and 37 lesions on double dose delayed CT.⁷ Recent experience with MRI has shown the further advantage of high dose gadolinium chelate contrast administration in the detection of intracranial metastatic disease.⁸ In one such study, which compared 0.1 and 0.3 mmol kg⁻¹ doses, the higher dose resulted in the detection of 46 new lesions in 19 of 27 patients.⁹

With extra-axial brain lesions, contrast administration is often crucial for lesion identification. Small meningiomas and nerve tumors, in particular acoustic neuromas, are often isointense with brain on precontrast studies, and can thus be difficult to detect or clearly marginate on precontrast MRI alone (Figure 3). That these tumors are often small, with little

Figure 1 Glioblastoma multiforme. The contrast medium delineates the extent of blood–brain barrier disruption associated with primary intra-axial neoplasms of the central nervous system and assists in characterizing these lesions. The pattern of enhancement is often useful in narrowing the differential diagnosis. This middle-aged female presented with persistent headaches. (a) The precontrast T_1 -weighted axial scan reveals a large low signal intensity lesion in the right frontal lobe with significant mass effect. (b) Surrounding edema is best demonstrated on the T_2 -weighted image. (c) Postcontrast, the mass exhibits a thick irregular ring of enhancement with central necrosis. This constellation of findings suggests the diagnosis of a high-grade glial cell tumor

Figure 2 Metastatic breast carcinoma. The contrast medium aids in identification of metastatic lesions which may be masked by edema or are too small to be visualized on a noncontrast examination. This middle-aged female with a primary breast malignancy presented with sudden onset of left-sided weakness. (a) The precontrast T_1 -weighted axial image demonstrates edema in the white matter surrounding an ill-defined mass. The (b) postcontrast image confirms the presence of a mass, with enhancement seen on the basis of blood–brain barrier disruption

mass effect, compounds the problem of their identification on precontrast scans. With extra-axial lesions, contrast enhancement is dependent upon intrinsic vascularity. This is unlike the situation with intra-axial lesions, where lesion enhancement depends principally upon disruption of the normal blood–brain barrier.

In cerebral ischemia, intravenous gadolinium chelate administration routinely provides information with regard to dating of the lesion (Figure 4). Also provided are important data relative to lesion characterization, improving differential diagnosis. In a minority of cases, principally certain subacute infarcts, lesions may not be visualized without contrast administration. The pattern of abnormal contrast enhancement in cerebral infarction is dependent upon the time of imaging relative to ictus. In early infarction, days 1–3, abnormal intravascular enhancement can be noted secondary to slow flow or vascular engorgement. From days 2 to 6, meningeal enhancement adjacent to the area of cortical infarction can be noted, although this finding is less common than intravascular enhancement. Seven to fourteen days following ictus, parenchymal enhancement can be noted secondary to blood–brain barrier disruption. This finding may persist as long as 6–8 weeks after clinical presentation. In other vascular diseases, contrast administration can also provide important ancillary information. Enhancement is routinely observed post-contrast in regions of slow flow, improving the depiction of

giant aneurysms, the venous component of arteriovenous malformations, and venous angiomas.

In cerebral ischemia, and other disease states which affect brain perfusion, a new application of gadolinium chelates has recently emerged. Unlike conventional magnetic resonance contrast studies which rely principally upon detection of differences in structure, perfusion studies provide functional information. To obtain these data, the contrast agent is given as a bolus, with higher doses being more efficacious, and the first pass of the gadolinium chelate observed through the brain with rapid dynamic imaging.¹⁰ In this manner, either qualitative or quantitative information regarding cerebral blood volume can be obtained.

With infection and other inflammatory disorders, intravenous gadolinium chelate administration improves lesion characterization and makes possible the assessment of lesion activity (Figure 5). Rarely, a lesion will not be identifiable other than following contrast administration. Contrast enhancement is particularly important for the identification of inflammatory disease of the meninges. In this application, contrast enhanced MRI is markedly superior to contrast enhanced CT. In the demyelinating diseases, and in particular multiple sclerosis, contrast administration is employed when the assessment of disease activity is important. Active or acute lesions demonstrate disruption of the blood–brain barrier, and thus positive contrast enhancement on T_1 -weighted MR images (Figure 6).

Figure 3 Right intracanalicular acoustic neuroma. This patient presented with a 5-month history of vertigo and tinnitus. Inspection of axial (a) T_2 -weighted, together with (b) pre- and (c) postcontrast T_1 -weighted, scans illustrates the value of contrast administration in the visualization of small extra-axial tumors. If it were not for the subtle expansion of the internal auditory canal on the precontrast images, this lesion could be easily overlooked. The postcontrast image reveals intense homogeneous enhancement of the right seventh and eighth nerve complex, making possible the diagnosis of an acoustic neuroma

Figure 4 Acute right posterior cerebral artery infarction. Contrast administration in brain infarction improves lesion characterization, providing information that points to the diagnosis of an infarct. It also permits dating of the event, and at times enables recognition of a lesion which would otherwise go undetected. This patient presented with sudden onset of left visual problems of 2 days' duration. Illustrated are the (a) T_2 -weighted, (b) precontrast T_1 -weighted and (c) postcontrast T_1 -weighted axial images. There is subtle effacement of sulci in the right posterior cerebral artery (PCA) territory on the precontrast T_1 -weighted image with corresponding abnormal high signal intensity on the T_2 -weighted image. Postcontrast, intravascular enhancement (arrow) is noted in the PCA distribution, consistent with the diagnosis of an acute cortical infarct

Figure 5 Infection. (a) T_2 -weighted, (b) precontrast T_1 -weighted, and (c) postcontrast T_1 -weighted axial images are shown from the MRI exam of an HIV-positive young adult male presenting with mental status changes. Gadolinium chelate administration improves detection of the two ring-enhancing lesions in the right frontal lobe, which are obscured by edema on the precontrast images. Although the findings are nonspecific, the diagnosis of toxoplasmosis should be considered in this clinical setting. In this case, the use of contrast allowed the identification of a treatable cause of the patient's symptoms

Figure 6 Multiple sclerosis (MS). The (a) precontrast T_1 -weighted, (b) postcontrast T_1 -weighted, and (c) precontrast T_2 -weighted axial images, from a young adult female (with a 6-day history of double vision), demonstrate several points about the usefulness of contrast in imaging patients with suspected MS. The precontrast T_1 -weighted image is essentially normal. After administration of a gadolinium chelate, a single focus of enhancement is identified in the periventricular white matter on the right. The T_2 -weighted image shows a corresponding focus of high signal intensity, as well as several other high signal intensity foci which did not enhance. Active MS plaques enhance after contrast administration, while older inactive plaques do not. Both will appear as high signal intensity abnormalities on T_2 -weighted images. Contrast administration in this case aids not only in establishing the diagnosis, but also in determining which lesions are active and which are not

3 CLINICAL APPLICATIONS IN THE SPINE

Although MRI became accepted as a major clinical tool for examination of the brain in the early 1980s, it was not until later in that decade that technical developments permitted routine diagnostic quality spine examinations. Limited by these technical constraints, the first use of contrast agents in spine imaging also postdated that in the brain by several years. This sequence of events continues to have impact today, with the clinical knowledge base relative to contrast use in the spine still lagging behind that in the brain. Thus contrast use is limited in the spine in many clinical practices to a small subset of patients, despite the existence of studies demonstrating broader clinical application.

To date, in spine MRI, contrast media play their greatest role in the postoperative back, infection, and intradural neoplastic disease. Recurrent back pain following lumbar discectomy is a major clinical problem, with many different etiologies. With the appropriate findings on physical examination, the identification of a recurrent disk herniation or the presence of residual disk material is an indication for reoperation. However, on precontrast MRI, scar tissue and disk material can be difficult to differentiate. In the first 10–20 min following intravenous gadolinium chelate administration, differ-

entiation between these two entities is permitted (Figure 7). Postoperative epidural scar is a relatively vascular tissue, with enhancement seen postcontrast due to diffusion of the agent into the extravascular space via leaky junctions and endothelial discontinuity. Disk material per se is avascular, and will not demonstrate enhancement. It is important to recognize that the degree of enhancement seen in scar tissue is moderate, being substantially less than that seen in most intracranial disease processes. Furthermore, the timing of postcontrast examinations is critical, with delayed scans allowing for diffusion of the contrast agent into disk material and rendering impossible the distinction between scar and disk.

In infection involving the spine, gadolinium chelate administration provides information principally relative to the extent of involvement of soft tissue and the disease activity (Figure 8). Although characteristic changes on T_2 -weighted examinations have been described specifically in disk space infection, the ability to diagnose infection is, without question, markedly improved by contrast administration. A prospective clinical study in the early 1990s concluded that gadolinium chelate enhanced MRI provides excellent anatomical delineation of disease involvement, gives increased diagnostic confidence, enables localization of portions of a mass most likely to provide diagnostic biopsy, and identifies active infection that has not responded to antibiotic infection.¹¹
